Preface

In the last decade, many textbooks of pediatrics have been published in India. However, most were targeted towards undergraduates and general practitioners. The number of students opting for postgraduate courses in pediatrics is on the rise. Currently, most postgraduates in pediatrics augment their knowledge by reading and referencing to textbooks published abroad. Many of the Western textbooks are very detailed and provide an important amalgamation of clinical pediatrics with the major advances in genetics, genomics, physiology, diagnosis, imaging, and therapeutics. However, the "state-of-the-art" on the care of the normal and ill neonate, child, or adolescent as presented in these textbooks differ from that practiced in India or South Asia. While these books provide a detailed description of most disorders seen in children, they unfortunately do not provide both evidence-based medicine and astute personal clinical experiences from India. The focus is missing on the core issues relevant in the Indian context, i.e., growth, nutrition, immunization, development, newborn and adolescent health, and programmatic and social issues in child health. The need for a comprehensive postgraduate textbook, which can be adapted to Indian needs, has been recognized and expressed for some time now.

Rapid strides in medicine and technological advances in biological sciences were witnessed in the last decade. Advances in preventive and therapeutic care have opened new prospects for care of children. However, substantial improvements in quality of life have been limited to those with access to healthcare. Poverty, ignorance, war, bioterrorism, misplaced priorities and the lack of political will have prevented many children throughout the world, benefitting from these significant advances. Despite advances in infectious diseases, newer vaccines and preventive neonatal care, mortality and morbidity continue to be unacceptably high. Our priorities for care of children are often different from the developed world. Also, medical advances and good clinical practice must always be coupled with effective advocacy. These aspects need to be addressed in a postgraduate textbook, as current postgraduates are the future decision makers in our country.

It is our earnest wish and hope that the postgraduate textbook will help to fill the long-felt vacuum. It attempts to provide the essential information that postgraduates throughout India need to capture to effectively address the health problems that our children and youth may face in the times to come. Our objective is to be comprehensive yet concise and reader friendly, embracing both the new advances in science as well as the time-honored art of pediatric practice. Both Indian and international experts in respective fields have provided the details that have been further scrutinized for exposition and usefulness to pediatric postgraduates by a chosen team of eminent academicians. We have liberally included tables, line diagrams, images, clinical photographs, illustrative figures, flow charts and algorithms in the main text. The book is divided into 10 major Parts and further arranged into 51 Sections and Annexures to cover all aspects of postgraduate pediatric curriculum. Themes which have major public health relevance for India are extensively covered. It is almost impossible to cover all pediatric problems with the same degree of detail, and hence a careful balance has been made in the details of description of diseases and their management to the needs of the students, and to keep the book to a manageable size. Summary points "In A Nutshell" are provided at the end of each chapter. Selected recent references—mostly leading articles, reviews and position statements—are provided for more detailed information, if desired by the student or the teacher.

Some kind of overlap is unavoidable in a book of this magnitude, with 725 plus minds working on more than 600 chapters simultaneously. We have strived hard to minimize it. We have also tried our best to keep all the chapters on an even keel despite the unavoidable diversity of disciplines, thoughts, experience, and expressive capabilities of the distinguished authors and section editors, from all over the globe. The book would not have been possible but for the support that we received from these erudite contributors. We are indebted to them for their knowledge, introspection, and judgment during the entire process. Together we have worked hard to produce a compilation that will be helpful to those who desire to learn more about child health in India and thus provide better care for children.

Rakesh Lodha

Acknowledgments

40.40 Preventive Cardiology in the Young

S Sivasankaran

42.11 Status Epilepticus

We wish to acknowledge the help and support provided by Lisa Garrity, Pharm D.

Ravindra Arya, Katrina Peariso

42.24 Childhood Ataxia

I wish to acknowledge that a significant part of the discussion on genetic and inherited metabolic disorders associated with ataxia was included in a prior work on the same subject published for e-medicine. The material has been modified considerably to fit into a pertinent discussion on childhood ataxia. I also wish to acknowledge and thank contributors to the prior work; Professor Cheryl Greenberg (MD FRCPC), Division of Genetics and Metabolism, University of Manitoba; Dr Chitra Prasad (MD FRCPC FCCMG), Genetics and Metabolic Disorders, Program of South-Western Ontario; Professor M Jog (MD FRCPC), Division of Clinical Neurosciences, University of Western Ontario.

Asuri N Prasad

47.1 Common Visual Problems

I wish to acknowledge the contribution of Dr Ankush Mutreja in preparation of Flow charts 1 to 5 included in this chapter.

Kirti Singh

48.11 Cutaneous Manifestations of Collagen Vascular Diseases

I acknowledge Dr Ipsa Niyant Pandya, postgraduate student, Department of Skin and Veneral Diseases, Baroda Medical College, Vadodara, Gujarat for her invaluable contribution.

Yogesh S Marfatia

FROM THE EDITORIAL DESK

Ms Anju Kumari: Secretarial assistance.

Dr Sakshi Sachdeva: Editorial assistance.

We would like to extend our thanks and appreciation to Shri Jitendar P Vij (Group Chairman) and Mr Ankit Vij (Group President) for their vision and belief in this project; Mr Tarun Duneja (Director–Publishing), Mr KK Raman (Production Manager), Ms Samina Khan (Exec. Assistant to Director–Publishing), Mr Sunil Kumar Dogra (Production Executive) and Mr Neelambar Pant (Production Coordinator), for their unflinching support and tireless work. We would also like to thank the entire staff of M/s Jaypee Brothers Medical Publishers (P) Ltd, New Delhi, India, especially Ms Shalu Mann (Medical Editor); Mr Gurnam Singh (Sr Proofreader); Mr Sarvesh Kumar, Ms Kamlesh Rawat, Mr Gyanendra Kumar (Proofreaders); Mr Rajesh Kumar, Mrs Yashu Kapoor, Mr Rakesh Kumar (Typesetters); Mr Satender Singh, Mr Sumit Kumar, Mr Rohan Prasad (Graphic Designers); and Mr Joginder Kumar for delivery of the proofs.

Chapter 41.1

Anatonmy and Physiology

M Vijayakumar, Arvind Bagga

ANATOMY

The two kidneys lie on either side of the vertebral column retroperitoneally on the posterior wall of the abdomen. They grow rapidly in the first year of life, from a birth length of 4.5 cm to an adult value of 11 cm. The outer 1–2 cm thick region of the kidney is called the cortex; the inner region is called the medulla with renal pyramids and the intervening renal columns constitute medulla. The base of the pyramids is at the corticomedullary border and the apices are the papillae, which project into minor calyces that join to form 3–4 major calyces and then the renal pelvis **(Fig. 1)**. The smooth muscle on walls of the calyces, pelvis and ureters contract to propel the urine toward the urinary bladder.

The main renal artery divides into five segments, which subsequently branch at the sides of the pyramids to form the interlobar artery, the arcuate artery, the interlobular artery and the afferent arteriole, which lead to glomerular capillaries. The efferent arteriole is formed by coming together of glomerular capillaries, which ultimately end in a secondary capillary network; the peritubular capillaries, which supply blood to the nephro . e venous system runs parallel to the arterial system, with interlobular,

arcuate, interlobar and renal veins. The lower splanchnic nerves give rise to sympathetic nervous fibers, which travel through the lumbar ganglion to the kidney. Renal blood flow is reduced by stimulation of the sympathetic nervous system due to intrarenal vasoconstriction. The renin-angiotensin aldosterone system is also stimulated by the sympathetic nervous system.

Nephrons

Nephrons are the functional unit of the kidney, each kidney having 1–1.2 million nephrons. Each nephron is composed of a glomerulus, proximal tubule loop of Henle, distal tubule and the collecting ducts **(Fig. 2** . e glomerulus filters blood, while providing a barrier to passage of protein and cells into the urine. The glomerulus consists of a network of capillaries supplied by the afferent arteriole and drained by the efferent arteriole. The endothelial cells of the glomerular capillaries are covered by the glomerular basement membrane and surrounded by foot processes of podocytes, constituting the filtration barrier. The fenestrated endothelium is freely permeable to water, small solutes and ost proteins, but is not permeable to the cellular components. Glycoproteins on the endothelial cells confer a negative charge, which prevents filtration of negatively charged proteins. The endothelial cells also produce vasoactive substances, such as angiotensin, prostaglandins, nitric acid, endothelin-1,

bradykinins and glucocorticoids which are important in controlling renal blood flow. The basement membrane, a porous matrix of negatively charged proteins including type IV collagen, laminin, proteoglycans and fibronectin, is an important barrier to plasma proteins. Podocytes have foot processes that interdigitate to cover the basement membrane and are separated by filtration slits. These slits are bridged by a porous diaphragm composed of several proteins including nephrin, podocin, actinin 4 and CD2AP.

Glomeruli of the superficial nephrons are located in the outer cortex; their loop of Henle is short and its efferent arteriole branches into peritubular capillaries that surround the nephron segments of its own and adjacent nephrons. This capillary network enables delivery of substances to the nephron for secretion and return of reabsorbed water and solutes to the circulation. At the corticomedullary junction are the juxtamedullary nephrons, which have a long loops of Henle extending deep into the medulla. The efferent arteriole forms both a network of peritubular capillaries and also number of vascular loops called the vasa recta deep in the medulla. The long loops of Henle and its vasa recta serve to concentrate and dilute the urine.

Juxtaglomerular Apparatus

The juxtaglomerular apparatus is composed of thickened epithelial cells of the afferent arteriole (granular cells), specialized cells lining the wall of the distal tubule (macula densa) and the extraglomerular mesangial cells. Activation of rennin-angiotensin-aldosterone and sodium conservation takes place through the juxtaglomerular apparatus.

The glomerular filtrate enters the tubule as tubular fluid wherein reabsorption and secretion of solutes, electrolytes and water occurs along with some amount of diffusion to adjust the urinary composition and maintain the homeostasis of body fluid. Each nephron segment has specific transport functions. Almost all cells in the nephron have a single nonmotile primary cilium, which protrudes into the tubular fluid. Primary cilia act as mechanosensors that sense changes in flow rate of the tubular fluid, and chemosensors that sense or respond to compounds in the surrounding fluids and initiate calcium dependent signaling pathways including those that control kidney cell function, proliferation, differentiation and apoptosis. The process of reabsorption of solutes, electrolytes and water from the tubular fluid to blood across the renal tubular cell membrane and secretion from the peritubular capillary blood to tubular fluid is the result of specialized membrane carrier proteins called transporters, through specialized channels or by diffusion. Active transporters are Na^+/K^+ ATPase, Ca^{2+} ATPase, H^+/K^+ ATPase and H^+ ATPase. The passive transporters are the cotransporters (e.g., $Na^+/K^+/Cl^-$ and Na^+ glucose) and exchangers (Ca^+/Na^+ and H^+/Na^+).

PHYSIOLOGY

Functions of the Nephron

The followings are essential functions of the nephron:
1. Regulation of osmolality through excretion of osmotically dilute or concentrated urine.
2. Regulation of concentration of numerous ions in blood and plasma like Na^+, K^+, Ca^{++}, Mg^{++}, Cl^-, HCO_3^-, phosphate and sulfate.
3. Regulation of acid base balance through excretion of H^+ when there is excess acid, or HCO_3^- when there is excess base, maintaining the acid base status.
4. Regulation of extracellular fluid volume by controlling excretion of Na^+ and water.
5. Regulation of blood pressure by modifying urinary Na^+ excretion and secreting various substances like renin, which modulate blood pressure.

6. Elimination of metabolic waste products like urea, the main nitrogen containing product of protein metabolism, uric acid, the end product of purine metabolism, and creatinine, the end product of muscle degradation.
7. Elimination of drugs and toxic compounds.
8. Production of hormones like erythropoietin and $1,25(OH)_2$ vitamin D3 that are important in maintaining hemoglobin concentration and bone health.
9. Degradation of polypeptide hormones like insulin, glucagon, and parathormone.
10. Ammonia synthesis, which plays a vital role in acid base balance.
11. Synthesis of substances affecting renal blood flow and Na^+ excretion: arachidonic acid derivatives, prostaglandins, thromboxane A2 and kallikrein.

Specific Functions

The modulations in afferent and efferent arteriolar tone affect the intracapillary pressure which in turn intrinsically regulates the glomerular filtration rate (GFR). The GFR is maintained at constant level over a wide range of blood pressure by the process of autoregulation. In the proximal tubules isonatremic reabsorption of tubular fluid occurs, where sodium and water reabsorption is predominant. The thick ascending limb of loop of Henle is a diluting segment where sodium chloride is increasingly reabsorbed but not water. The distal nephron, derived from the original ureteric bud, responds to hormones that regulate volume osmolality and potassium concentration. The junction between the diluting and concentrating segments at the juxtaglomerular apparatus is the point where tubular functions decide the rate of glomerular filtration.

Seventy to eighty percent of the filtered salt and water is reabsorbed at the proximal tubule **(Fig. 3)**. This is an active process and the energy is derived from Na^+-K^+-ATPase pump. Water and sodium reabsorption at this site is aided by hyperoncotic peritubular capillary fluid. Cotransport of glucose, phosphate and amino acids are important at this site. Hydrogen secretion by the proximal epithelial cell is important for reabsorption of filtered bicarbonate **(Fig. 4)**. Carbonic anhydrase is important for this function in addition to the sodium gradient. If sodium gradient fails due to dysfunction, as in Fanconi syndrome, proximal tubular reabsorption of bicarbonate, glucose, phosphate and amino acids are impaired.

Sodium is actively pumped into renal interstitium from the thick ascending limb of Henle. Water cannot go along with sodium due to water proofing effect of Tamm Horsfall proteins secreted at this site. The tubular fluid osmolality is less than 80 mOsm/kg but interstitium becomes hyperosmolar with 1,400 mOsm/kg tonicity at the renal papillae, which is essential for subsequent water reabsorption from the collecting ducts. Tubuloglomerular feedback at the juxtaglomerular region is the process that regulates tubular and hence glomerular function at this point of the tubule. At this site, the specialized tubular cells of the macula densa relate closely with the juxtaglomerular apparatus and also the afferent and efferent arterioles.

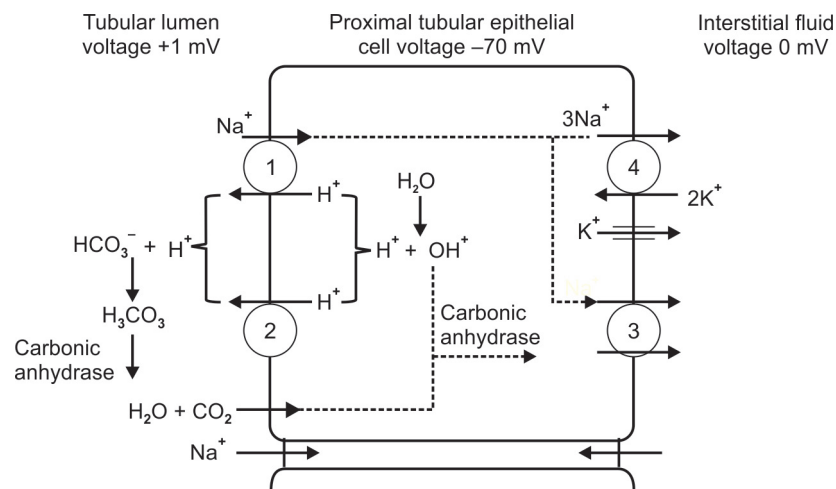
Distal convoluted tubule (DCT) is very important for the fine tuning of the acid-base regulation of the body and for reabsorption and secretion of salts **(Fig. 5)**. Three types of cells are present here. Principal cells of the DCT regulate potassium secretion into and sodium reabsorption from the urine and are dependent on aldosterone as well as on the delivery of sodium to the lumen of the DCT to be exchanged with potassium. The epithelial sodium channels (ENaCs), which are located on the apical aspects of the cell, are essential for the rate-limiting step for sodium recovery and are synthesized in response to aldosterone. The second important cell is the intercalated cell which regulates the secretion of hydrogen ions into the urine in exchange for potassium. The final cell type is
Figure 3 Renal tubular handling of sodium and potassium. The major sites of reabsorption are shown, with percentage of filtered cation in parenthesis


Figure 4 Reabsorption of bicarbonate in the proximal tubule. Protons (H^+), secreted into the lumen through the sodium (Na^+) H^+ antiporter (1) and H^+ ATPase (2), combines with HCO_3^- to form H_2CO_3 that under the action of luminal membrane carbonic anhydrase dissociates to H_2O and CO_2. The CO_2 travels across the membrane into the cell where it combines with OH^- to generate HCO_3^-. The HCO_3^- and Na^+ cross the basolateral membrane using the Na^+/HCO_3^- symporter (3). Na^+ also exits the cell via the Na^+/K^+ ATPase (4). Electrogenic H^+ secretion generates a small lumen positive voltage, which creates current flow across the paracellular pathway

sodium chloride cotransporter, which are inhibited by thiazides. This cell is important in the reabsorption of calcium from the urine.

Healthy children on salt restriction can reabsorb 99% of the sodium from the nephron with only 1% being excreted. In preterm infants, 5% of the filtered sodium is excreted. Renin angiotensin system is not the only stimulus for aldosterone.

Hyperkalemia can also stimulate aldosterone secretion, thereby controlling its urinary excretion. Collecting ducts, derived from the ureteric bud, are responsible for reabsorption of water through the action of vasopressin on water permeable channels called aquaporins. Aquaporins, especially aquaporin 2, rapidly move from intracytoplasmic vesicles into the plasma membrane

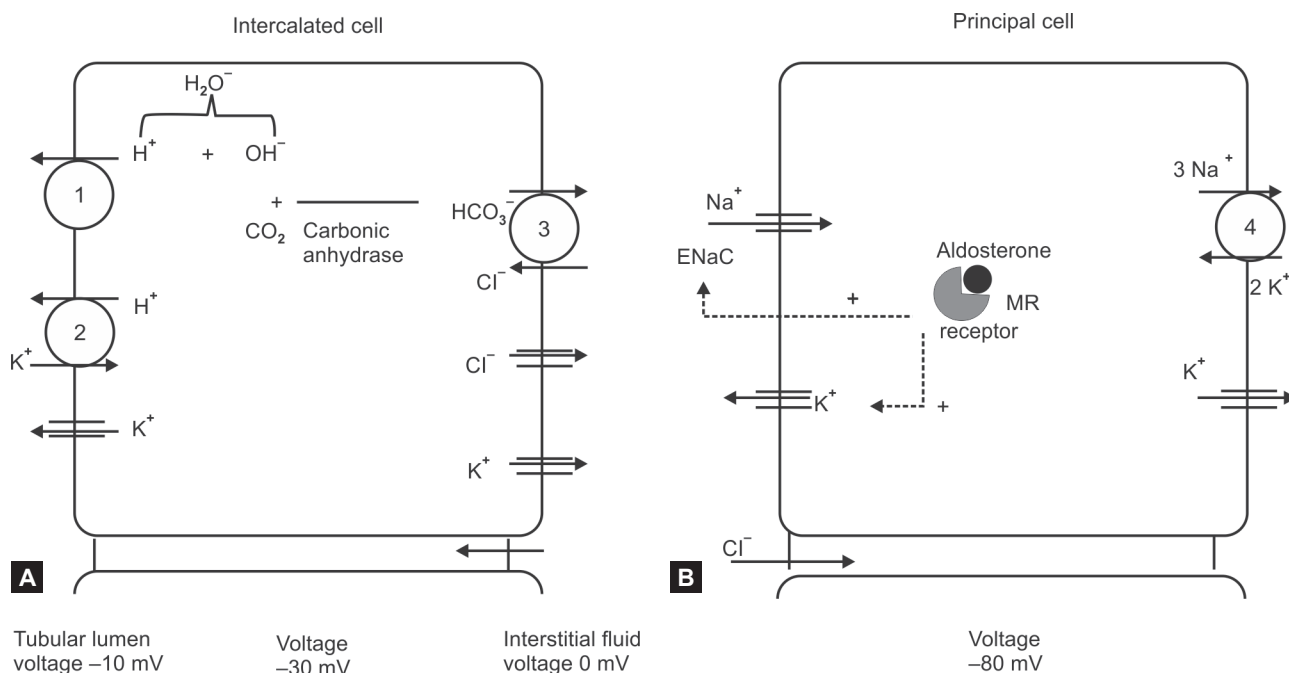
Intercalated cell

Principal cell

Tubular lumen voltage −10 mV

Voltage −30 mV

Interstitial fluid voltage 0 mV

Voltage −80 mV


Figures 5A and B Mechanism of acidification and potassium excretion in the distal renal tubules. (A) The intercalated cells of the cortical collecting ducts secrete H^+ through the H^+ ATPase (1) and H^+/K^+ ATPase (2), independent of Na^+ transport. The hydroxyl (OH^-) ions generated in the cell through H^+ secretion exit the cell by the HCO_3^-/Cl^- exchanger (3). The secreted H^+ is buffered by luminal ammonia forming NH_4^+ and phosphate (titratable acids), to prevent a drop in luminal pH that would prevent further H^+ secretion; (B) Principal cells mediate sodium (Na^+) absorption and potassium (K^+) transport. The apical membrane contains an amiloride sensitive Na^+ channel (ENaC); Na^+ exits basolaterally *via* Na^+/K^+ ATPase (4). Sodium transport creates a lumen negative transepithelial potential that increases the rate of H^+ secretion by intercalated cells. Aldosterone binds to the mineralocorticoid (MR) receptor and enhances Na^+ absorption and H^+ and K^+ secretion

of the collecting ducts in response to vasopressin. Binding of vasopressin to vasopressin receptors leads to activation of adenylyl cyclase, which increases intracellular cyclic AMP. Thereafter activation of cAMP-dependent protein kinase A mediates protein phosphorylation, which triggers exocytic insertion of AQP2 channels into the apical membrane. These channels increase water permeability of the apical membrane, facilitating water transport. Water moves down an osmotic gradient from the dilute urine arriving in the distal nephron to the hyperosmolar medullary interstitium surrounding the collecting ducts. The maximum urine concentration capacity depends on the presence of vasopressin, the integrity of vasopressin 2 receptors and aquaporin assembly, and high concentration of medullary interstitial solute constituted chiefly by sodium and urea.

IN A NUTSHELL

1. Glomerular capillary hydrostatic pressure generates a protein-free filtrate of plasma into Bowman's capsule, with the glomerular filtration rate determined by relative constriction of afferent and efferent arterioles.
2. The proximal tubules reabsorb 65% of the filtrate.
3. The impermeability of the thick ascending limb in Henle's loop is responsible for medullary interstitial hypertonicity, which is important for urinary concentration.
4. The distal tubule is involved in aldosterone controlled sodium reabsorption and Na^+/K^+ exchange.
5. Cells of the distal tubule and collecting ducts secrete H^+ ions leading to maximum urine acidification.
6. Water is reabsorbed in the collecting ducts in response to ADH collecting ducts in response to ADH.

Chapter 41.2
Investigations for Kidneys and Urinary Tract
Susan Uthup, Jyoti Sharma

URINE EXAMINATION

Urinalysis is a simple, quick and inexpensive investigation. Urine specimens should be fresh and clean-voided midstream in older children.

Urine Macroscopic Examination

Depending on the concentration of urine, its color varies from pale yellow to amber. Red or tea-color urine suggests the presence of blood, hemoglobin, myoglobin, porphyrin, or nonpathologic pigments (beets, food color or medication). Blue to green suggests the presence of biliverdin or *Pseudomonas* infection. Urine is normally clear, but can be turbid in the presence of leukocytes, epithelial cells, bacteria, or crystals.

Dipsticks are commercially available, chemically impregnated reagent strips that employ a colorimetric change for pH, specific gravity, protein, blood, glucose, ketone, leukocytes, and nitrites in the urine. The strip should not be dipped for more than a few seconds in the urine; excess urine should be blotted off on the edge of absorbent paper to prevent mixing of reagents and the specific tests should be read at the appropriate time.

Specific gravity ranges from 1,001–1,035 and may be measured by a dipstick, refractometer or a urinometer. It reflects the concentrating and diluting ability of the kidney and under normal conditions, the hydration status. A low specific gravity is seen in polydipsia and diabetes insipidus; in a dehydrated child, a low value (< 1,007) represents a concentrating defect. When the kidneys can neither dilute nor concentrate the urine, specific gravity becomes fixed at 1,010 (isosthenuria).

Urinary pH can be estimated from a fresh urine specimen using a reagent test strip or a pH meter; it usually ranges from 5.0 to 8.0. Estimation of urinary pH is important in diagnosing renal tubular acidosis. Therapeutic urinary alkalinization is recommended in the management of uric acid and cystine stones, and management of certain poisonings (salicylates, barbiturate and methotrexate), rhabdomyolysis and tumor lysis syndrome.

Hemoglobin Urine dipsticks are sensitive to urine red cells, free hemoglobin and myoglobin.

Glucose is not usually present in the urine. Glucosuria can occur when there is hyperglycemia (plasma glucose concentration > 180–200 mg/dL) or reflect a defect in proximal tubule cells to reabsorb a normal filtered glucose load. Glucosuria without hyperglycemia may occur as an isolated defect due to a mutation in the SGLT2 transporter or, more commonly, as part of a generalized proximal tubule cell dysfunction (phosphaturia, aminoaciduria and bicarbonate wasting) referred to as Fanconi syndrome. Reagent test strips impregnated with glucose oxidase only detect glucose. Other sugars, such as galactose, lactose, fructose and mannose, can be detected by the Benedict test.

Nitrite and leukocyte esterase: Escherichia coli, Enterobacter, Citrobacter, Klebsiella, and *Proteus* species are able to reduce dietary nitrate to nitrite. Positive nitrites in the urine are strongly suggestive of the presence of a significant number of bacteria, and a urine culture should be performed. Because bacteria require 4 hours to convert nitrate to nitrite, a false negative can occur if the urine has not been present in the urinary tract for sufficient time. Dipsticks detect leukocyte esterase, an enzyme found in neutrophils, and a positive test suggests the presence of leukocyturia.

Urine Microscopic Examination

Approximately 10 mL fresh urine is centrifuged for 5 min, the supernatant decanted, and the remaining drop examined on a clean slide for presence of casts, cells, crystals and bacteria.

Red blood cells Hematuria is defined as the presence of more than five red blood cells (RBCs) per high power field in a centrifuged urine or positive dipstick test for blood. In a patient who has urine that appears grossly bloody, a strongly positive dipstick with minimal RBCs visualized on microscopy suggests presence of myoglobin (rhabdomyolysis) or hemoglobin (intravascular hemolysis). Urine microscopy is useful in determining the etiology of hematuria since presence of dysmorphic RBCs (RBCs with membrane blebs, an irregular surface) and RBC casts suggests a glomerular disease.

White blood cells Greater than five white blood cells per high-power field is considered abnormal. Neutrophils in urine may be due to UTI, proliferative glomerulonephritis (GN), interstitial nephritis calculi or fever. Epithelial cells, i.e., renal tubular cells, transitional cells, and squamous epithelial cells may be observed in normal urine. Increased numbers of renal tubular cells may be seen with acute tubular injury (acute tubular necrosis, acute transplant rejection, and exposure to nephrotoxic agents).

Bacteria in the urine sediment in an asymptomatic child are most likely due to contamination with normal flora from the external urethral meatus or vagina. When seen in an unspun fresh sample, the presence of bacteria is highly suggestive of significant bacteriuria.

Casts are best seen in freshly voided unspun urine as cellular casts can dissolve within 30 min in acidic urine, within 10 min in alkaline dilute urine and centrifugation may damage them. They are formed in the lumen of distal convoluted tubules and collecting ducts and consist of an organic matrix composed of Tamm-Horsfall mucoprotein with or without cellular elements. Hyaline casts are common and can be seen in normal individuals and in proteinuric states. They may appear waxy if lipid droplets are present. Granular casts consist of proteins and degenerated tubular cells and may be seen in GN, pyelonephritis, strenuous exercise, fever and malignant hypertension. RBC casts are pathognomonic of glomerular disease and leukocyte casts can be seen with pyelonephritis, interstitial nephritis or postinfectious GN.

Crystals appear after the urine stands for a period. Uric acid and calcium oxalate crystals may be seen in normal conditions; cystine crystals are seen in cystinuria. Sulfadiazine, aciclovir, indinavir, vitamin C and amoxicillin may cause crystal formation when high doses are used and there is concomitant dehydration. Calcium carbonate and amorphous phosphate and amorphous urates are of no clinical significance.

Urinary protein excretion Normally Tamm-Horsfall proteins are secreted by tubular cells of thick ascending limb of Henle. In glomerular disease, large amounts of albumin are lost.

ASSESSMENT OF GLOMERULAR FILTRATION

Blood urea is the primary metabolite derived from dietary protein and tissue protein turnover. Blood urea nitrogen is roughly one-half of the blood urea level (normal 20–40 mg/dL); the urea: creatinine ratio is 20–40:1. Disproportionate rise in blood urea compared to serum creatinine are seen in dehydration, upper gastrointestinal bleed, hypercatabolic states like sepsis, burns, crush injuries and in patients on steroids. Low urea levels are seen in starvation, low protein intake and severe liver disease.

Glomerular filtration rate (GFR) is the most commonly used measure of kidney function. Inulin clearance is considered the gold standard for measuring GFR, but is cumbersome to perform. Creatinine clearance (CrCl) measurement is widely used and correlates well with inulin clearance within the normal range of GFR; however, calculation requires timed urine collection. For practical purposes, plasma concentration of endogenously produced creatinine or cystatin C is used for estimation of GFR. The modified Schwartz formula is used for estimation of GFR.

GFR (mL/min/1.73 m^2) = k × height (cm) ÷ serum creatinine, where k = 0.41 in children 1–16 years old.

GFR is low in infancy and reaches normal adult level (118 ± 18 mL/min/1.73 m^2) by 2 years of age.

Cystatin C is a low molecular weight protein (13.36 KDa) produced by all nucleated cells with a stable production rate. Estimated by enzyme immunoassays or immunoturbidometry, this protein is influenced less by age, gender, and muscle mass than creatinine, and correlates better with GFR. Formulae have been proposed that provide an estimate of GFR.

ASSESSMENT OF TUBULAR FUNCTION

Plasma ultrafiltrate from the glomerulus enters the proximal tubule where 60–65% is reabsorbed. In disorders of the proximal tubule, excessive amounts of the solutes will be found in the urine. The fractional excretion of sodium and tubular reabsorption of phosphate is used to assess the integrity of the proximal tubules. Detection of glucosuria and aminoaciduria are indicative of proximal tubular disorder **(Table 1)**.

HISTOPATHOLOGICAL EVALUATION

Renal histopathology forms an integral part of diagnosis of certain renal disorders, e.g., crescentic GN and IgA nephropathy. The procedure is important for diagnosis and prognostication (e.g., steroid resistant nephrotic syndrome) and for planning management (e.g., steroid resistance, lupus nephritis). Under aseptic precautions, 2–3 cores of renal cortex are obtained with an 18-gauge needle. The sample is subjected to light microscopy, immunofluorescence and when indicated, electron microscopy.

IMAGING OF THE KIDNEYS AND URINARY TRACT

Ultrasonography

Ultrasound of kidneys, ureters and bladder is the most common initial imaging tool for evaluation of kidney diseases. The procedure is safe, easy to perform, noninvasive, painless, and relatively inexpensive. Renal location, contour, size, corticomedullary differentiation as well as the status of collecting system and bladder can be assessed easily **(Fig. 1)**. Repeated studies can be performed without the risk of radiation or contrast. However, the procedure is operator dependent, difficult to interpret and functional assessment is not possible. Renal vascularity and perfusion can be assessed by color Doppler. Antenatal ultrasound is a perfect screening tool for detection of renal anomalies including dysplastic kidney, hydronephrosis and posterior urethral valves. Ultrasound is used for evaluation of patients with congenital abnormalities of the kidney and urinary tract **(Fig. 2)**, urinary tract infection, hematuria, proteinuria, renal stones, abdominal mass, acute kidney injury and chronic kidney disease. The presence of small contracted echogenic kidneys with loss of corticomedullary differentiation points to diagnosis of chronic kidney disease. Renal biopsy and catheter drainage of the dilated urinary tract can be done under ultrasound guidance.

Plain X-ray

A plain radiograph of abdomen delineates the kidneys and urinary tract. A radiolucent halo outlined by perinephric fat outlines the kidneys. Radiopaque renal, ureteric or bladder calculi, vertebral anomaly, indwelling catheters and stents can be seen. Conventional X-ray can show skeletal abnormalities of mineral bone disease.

Figure 1 Ultrasound of a normal child's kidney showing hyperechoic medulla with sinus complex and hypoechoic cortex. The echogenicity is compared to the adjacent liver

Table 1 Assessment of tubular function

Test	Estimation/Formula	Interpretation
Fractional excretion of sodium (FENa)	$\dfrac{\text{Urinary sodium} \times \text{plasma creatinine}}{\text{Plasma sodium} \times \text{urinary creatinine}} \times 100$	Prerenal failure: FENa < 1% in children; < 2.5% in neonates Acute tubular necrosis: FENa > 2% in children; > 2.5% in neonates
Tubular reabsorption of phosphate %	$1 - \dfrac{(\text{Urinary phosphate} \times \text{plasma creatinine})}{(\text{Plasma phosphate} \times \text{urinary creatinine})} \times 100$	TRP < 85% indicates urinary phosphate wasting
Transtubular potassium gradient	$\dfrac{\text{Urinary potassium} \times \text{plasma osmolality}}{\text{Plasma potassium} \times \text{urinary osmolality}}$	Urinary sodium should be > 25 mEq/L and urine osmolality should be greater than plasma osmolality Hypokalemia: TTKG > 2.5 indicates renal potassium wasting Hyperkalemia: TTKG < 5 indicates hypoaldosteronism
Calcium excretion	24 hours urinary calcium	Normal < 4 mg/kg/day; < 0.1 mmol/kg/day
	Calcium/Creatinine ratio in spot urine specimen	Normal < 0.5 in neonates and infants; < 0.2 in older children
Chloride excretion	Estimated in random urine sample	Metabolic alkalosis: Urinary chloride > 10 mEq/L suggests renal chloride loss; < 10 mEq/L suggests gastrointestinal loss or volume contraction
Urine anion gap	Urinary sodium + potassium – chloride	Positive urinary anion gap in a patient with normal anion gap metabolic acidosis suggests renal tubular acidosis

Figure 2 Ultrasound showing hydronephrosis in a neonate. See the enlarged dilated renal pelvis and calyces

Figure 3 Voiding cystourethrography showing bilateral grade 4 vesicoureteric reflux in a child with recurrent urinary infections
Figure 4 Normal dynamic renal scintigraphy using DTPA. Note the first pass perfusion and function curves

Intravenous Urography

Intravenous urography (IVU) is excellent in giving anatomic details, but entails radiation exposure and use of contrast medium (urografin 3–4 mL/kg). Initial scout film of the IVU shows radiopaque stones and the bowel gas pattern. The renogram phase shows contrast uptake by renal parenchyma. Frontal films at 3 min and 15 min evaluate the upper urinary tract. Delayed films, at 24 hours, show fullness of the obstructed renal unit.

Voiding Cystourethrography

Voiding cystourethrography (VCUG) or micturating cystourethrography (MCU) helps to assess lower urinary tract. This is indicated in evaluation of antenatal hydronephrosis, urinary tract infections, suspected obstructive anomaly, voiding dysfunction and neurogenic bladder. It is used in diagnosis and grading of vesicoureteric reflux. Urinary tract infection should be ruled out prior to the procedure. Prophylactic antibiotic should be given 30 min before and 6 hours after the procedure. Bladder is catheterized and slowly filled with diluted contrast medium (volume based on bladder capacity). Assessment is done during the filling phase, with full bladder, voiding and after emptying **(Fig. 3)**. *Radionuclide cystography* is satisfactory for follow-up studies in patients with reflux since the radiation exposure is lower.

Computerized Tomography

Excellent anatomical details are obtained on computerized tomography (CT) scan. Radiation exposure, contrast toxicity and need for sedation are the limiting factors. CT scan is useful for evaluation of abdominal trauma, renal injury, intrarenal infections (renal abscess and perinephric collections) and renal tumors.

Renal Scintigraphy

Radionuclide scintigraphy helps to assess renal blood flow, global and single kidney GFR, renal structure and presence of scars. It is highly sensitive, noninvasive and uses less radiation compared to IVU and CT scan.

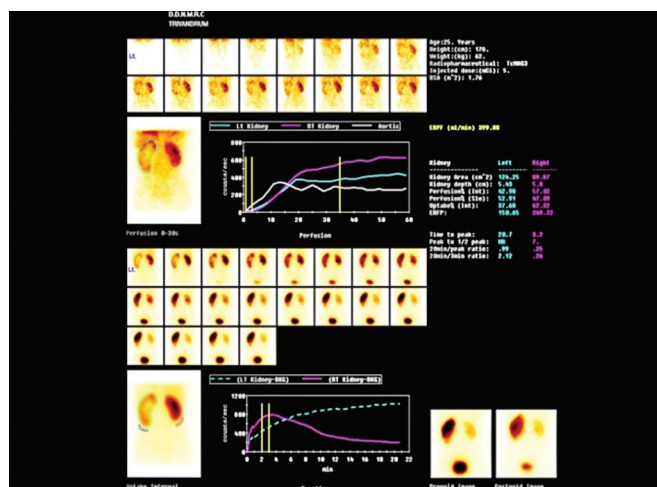
Renography Tc-labelled radiopharmaceutical is injected IV and its uptake and elimination by the kidney is monitored. Glomerular filtration agent, diethylenetriaminepentaacetate (DTPA), is used commonly. Three phases are described for quantifying the renogram. These include perfusion phase (0–30 s) representing first passage of the radioactive bolus into the kidney, parenchymal phase (40–160 s) representing glomerular filtration and the excretory phase (3–20 min) **(Fig. 4)**. The differential function of each kidney can be derived by the area or slope of the renal time activity curve. Furosemide renography is used in the evaluation of


Figure 5 Furosemide renography showing obstructed flow pattern in the left kidney
Figure 6 Static renography using DMSA showing areas of cortical uptake by normal kidneys

obstruction **(Fig. 5)**. Captopril renogram is used for evaluation of renovascular hypertension.

Renal static imaging Dimercaptosuccinic acid (DMSA) is concentrated in the renal tubules and gives excellent images of the cortex **(Fig. 6)**. It is useful to define areas of inflammation and is the reference investigation for detection of renal cortical scarring.

Magnetic Resonance Urography

Magnetic resonance urography gives both anatomic and functional information. It correlates well with furosemide renal scan and may be superior in terms of determining nonobstructive from obstructive hydronephrosis. The need for sedation, cost and need for specialized protocols limit the use of the investigation in children. Patients with reduced renal function may be at risk of nephrogenic systemic fibrosis with the use of gadolinium contrast.

IN A NUTSHELL

1. A carefully performed urinalysis on a fresh urine sample provides a great deal of information toward the diagnosis of renal disorders, while dipsticks are useful screening tools.
2. Estimation of GFR continues to rely on serum creatinine; Cystatin C is a similar molecule that rises early in acute kidney injury and correlates better with GFR.
3. Choice of tubular function tests should be tailored to the suspected disease.
4. Ultrasound of kidneys, ureters and bladder is the most common initial imaging tool.
5. Specific tests for imaging and radionuclide scans should be chosen judiciously depending on the information required.

Chapter 41.3
Congenital Anomalies of Kidneys and Urinary Tract
Shilpa Sharma, Aditi Sinha

Congenital anomalies of the kidney and urinary tract (CAKUT) result from abnormal embryonic development of the renal parenchyma or the developing collecting system or abnormalities in renal migration. While certain abnormalities require early evaluation and management, in others parental anxiety should be allayed and appropriate follow-up advised.

EPIDEMIOLOGY

Congenital anomalies of the kidney and urinary tract may be diagnosed during the prenatal period, in the neonatal age or during later childhood. These constitute approximately 20–30% of anomalies identified on antenatal ultrasound. Their incidence in live and stillborn infants is 0.3–1.6 per 1,000. However, it is not unusual for CAKUT to present in late childhood with urinary tract infections, abdominal lump or end stage renal disease.

PELVIURETERIC JUNCTION OBSTRUCTION

Hydronephrosis, or dilatation of the pelvicalyceal system, is commonly caused by functional or mechanical obstruction at the pelviureteric junction (PUJ). The obstruction may be discovered on prenatal ultrasound or present later in childhood with abdominal lump with or without dysfunction of the affected kidney.

Etiology

Pelviureteric junction obstruction may develop due to (1) an intrinsic defect (e.g., muscular deficiency at the PUJ, high insertion of ureter into pelvis, persistent ureteral folds, ureteral stenosis or hypoplasia, or angulation and adhesions at PUJ), (2) intraluminal obstruction (e.g., polyp, papilloma or valves), or (3) extraluminal compression (e.g., by aberrant vessels crossing over the ureter). In an unobstructed system, urine flows from the renal pelvis into the ureters by anatomical continuity and peristaltic contractions of the pelvis and ureter. Obstruction to flow causes rise in pelvic pressure from the baseline (5–25 cm water), pelvic dilatation and parenchymal injury.

Clinical Features

While a majority of cases are picked up on antenatal ultrasonography, PUJ obstruction may sometimes be detected incidentally on abdominal ultrasound. Most children with congenital PUJ obstruction remain asymptomatic throughout life. However, depending on the degree and duration of obstruction, they may present with: (1) renal lump, (2) flank pain, (3) urinary tract infection, (4) stone (due to stasis and/or infection), (5) Dietl crisis (an acute presentation with flank lump, nausea and vomiting relieved by passage of large amount of urine), or (6) hematuria (rare, usually after trauma). Renal failure is unlikely unless PUJ obstruction affects a solitary kidney or is bilateral.

Course

Over 50–70% cases of unilateral hydronephrosis detected on antenatal ultrasound are transient, resolving completely during follow-up without loss of renal function. Renal function remains stable in 20–30% of cases despite persisting hydronephrosis due to PUJ obstruction. Since renal function deteriorates in the remaining 10% of cases with significant PUJ obstruction, a close follow-up is essential, especially during the first 2 years to identify the subgroup of patients that requires surgery. About 5–10% cases of PUJ obstruction may have associated vesicoureteric reflux (VUR), unilaterally or bilaterally, requiring evaluation.

Investigations

The evaluation for antenatally detected hydronephrosis is summarized at the end of the chapter. Investigations in patients with suspected PUJ obstruction include estimation of blood levels of urea, creatinine and electrolytes, and urinalysis. Being noninvasive, *ultrasonography* is the preferred modality to evaluate for renal anomalies and hydronephrosis. It helps to differentiate hydronephrosis from tumor, multicystic dysplastic kidney and other cystic kidney diseases, while enabling assessment of abnormalities and/or compensatory hypertrophy of the contralateral kidney. 99mTc-diethylenetriaminepentaacetic acid (DTPA) is the preferred radiopharmaceutical for diuretic renography to determine differential function of and the pattern of excretion from the affected kidney. Differential function is considered normal when 40% or more, decreased if between 10% and 40% and poor if less than 10%. PUJ obstruction is confirmed if the renal scan shows significant delay in excretion and a persistent rising curve, with or without decrease in split renal function. Micturating cystourethrogram (MCU) is considered in presence of dilated ureter, bilateral hydronephrosis or following urinary infection. An intravenous urogram (IVU) is rarely required, unless suspecting duplex system, horseshoe kidney or ectopic ureter. Antegrade pyelography may be useful if vesicoureteric junction (VUJ) obstruction is suspected.

Management

Percutaneous nephrostomy (PCN) drainage is warranted in patients with infected hydronephrosis, tense hydronephrosis with differential function less than 10% and in a solitary kidney with PUJ obstruction and low function. Differential function is reassessed 2 weeks after PCN drainage in children with PUJ obstruction to look for change in renal function following drainage. This would help to identify the need for pyeloplasty versus nephrectomy.

Most patients with hydronephrosis do not require surgery. Indications for surgery in patients with PUJ obstruction include: (1) split renal function of less than 35–40% in the affected kidney along with delayed excretion and an obstructive renogram curve, (2) deterioration in split renal function from normal to less than 35–40% function or an absolute fall in differential function by greater than 10% during follow-up; (3) renal lump, recurrent infections and/or significant pain, (4) presence of horseshoe, pelvic or crossed fused kidney; and (5) anteroposterior diameter (APD) of renal pelvis greater than 25 mm on postnatal ultrasound. Anderson-Hynes pyeloplasty is the usual procedure done either by laparoscopy or by open surgery. The principles of surgery include complete excision of the abnormal segment of the upper ureter, excision of the redundant pelvis, a dependent drainage and a wide pelviureteric anastomosis. Complications include occurrence of urine leak, infection or hemorrhage and persistence of obstruction.

With timely diagnosis and needful intervention, the prognosis for PUJ obstruction is usually satisfactory provided the preoperative function is greater than 35%. Kidneys with preoperative function of less than 15% are unlikely to show improved renal function following surgery.

ECTOPIC AND HORSESHOE KIDNEY

Ectopic kidney refers to a kidney that does not normally ascend to the retroperitoneal renal fossa at the level of the second lumbar vertebra, the most common location being pelvis. The ectopic kidney fails to rotate normally, resulting in a shift of the renal axis, directing the renal pelvis anteriorly rather than medially. Kidneys that also cross the midline are referred to as crossed renal ectopy; this may occur with or without fusion to the contralateral kidney.

Renal fusion occurs when a portion of one kidney is fused to the other. The most common fusion anomaly is the horseshoe kidney, which involves abnormal migration of both kidneys along with fusion of one pole of each kidney. This differs from crossed fused renal ectopy, which usually involves abnormal movement of only one kidney across the midline with fusion to the contralateral kidney. In more than 90% cases, fusion occurs at the lower poles and two separate ureters are maintained that traverse over the isthmus or the anterior surface of the kidneys. Fusion anomalies seldom ascend normally and are typically located at L4-L5 lumbar vertebrae or in the pelvis.

Presentation and Management

Ectopic, fused or crossed fused ectopic kidneys are usually asymptomatic and diagnosed incidentally on antenatal or postnatal ultrasound. Symptoms related to urinary tract infection, obstruction and/or renal calculi. Ultrasonography is the initial investigation. About 80% cases with horseshoe kidneys may show hydronephrosis, chiefly due to associated VUR or obstruction of the collecting system. Diuretic renography is useful to rule out significant obstruction to outflow. Patients should be monitored for occurrence of hypertension, proteinuria and deranged renal function.

Most patients have an excellent prognosis without need for intervention. Patients with VUR may benefit from continuous antibiotic prophylaxis to prevent urinary tract infections. Kidneys with significant obstruction to urine outflow may require surgical intervention.

MEGAURETER

Megaureter, or ureter greater than 7 mm in diameter, may be primary (functional or anatomic abnormality of the ureterovesical junction) or secondary (secondary to bladder or urethral abnormalities, such as neurogenic bladder or posterior urethral valves). The pathogenesis of primary megaureter is uncertain, and appears to occur due to an abnormality or delay in the development of muscles in the distal ureter around 20 weeks of gestation, leading to formation of an aperistaltic segment and functional obstruction.

The diagnosis of primary megaureter is suggested by hydro-ureteronephrosis on ultrasonography. MCU and diuretic reno-graphy help to exclude VUR and/or obstruction, assess differential renal function, and exclude secondary causes of megaureter. Patients with symptoms and asymptomatic patients with obstructed megaureter require surgical intervention. Asymptomatic patients with nonrefluxing, nonobstructed megaureters or refluxing, nonobstructed megaureters are managed conservatively with monitoring for infections and serial ultrasounds.

ECTOPIC URETER

Ectopic ureter refers to presence of ureteral orifice that is caudal to the normal insertion on the bladder trigone. This occurs when the origin of the ureteral bud from the mesonephric duct is abnormally high and separation of the bud from the duct is delayed or does not occur. Almost 75–80% of ectopic ureters are associated with duplex (double) renal collecting systems and 10% cases are bilateral. In a duplex system, the cranial ureteral bud is associated with the lower renal pole, and the caudal bud with the upper pole. Renal hypoplasia or dysplasia is common. In boys, the ectopic ureter is always above the external urinary sphincter, with 50% located in the posterior urethra. In girls, the ureteric orifice is below the external sphincter in two-thirds cases.

Ectopic ureters are detected as an incidental finding on antenatal or postnatal ultrasonography. Patients may present during infancy with urinary tract infections. Due to the location of the ureteric orifice in relation to the urethral sphincter, girls, but not boys, have incontinence. Beyond the age of toilet training, boys present with urinary tract infections, flank pain, urgency, frequency or epididymorchitis, while girls may have continuous wetness. The diagnosis is made on ultrasound. Magnetic resonance urography or intravenous urography may help in resolving the diagnosis in difficult cases. Dimercaptosuccinic acid (DMSA) scintigraphy helps to detect reflux associated scarring, and locate an ectopic kidney. Diethylene triamine pentaacetic acid (DTPA) renography is useful for assessing differential function.

Treatment

Symptomatic patients often require surgery. The approach depends upon whether the collecting system is duplex or single, and the extent of renal function. Ectopic ureter in a duplex system may be associated with a dysplastic upper pole renal segment that requires excision along with the proximal ureter. If the polar segment has good function, the ectopic ureter is reimplanted into the bladder or anastomosed outside the bladder to the normal pole ureter (ureteroureterostomy). An ectopic ureter associated with a small poorly functional kidney may require nephroureterectomy. If renal function is preserved, the distal ectopic ureter is resected and reimplanted into the bladder.

BLADDER EXSTROPHY

Bladder exstrophy is characterized by a defect of the anterior abdominal wall, bladder and urethra below the umbilicus in which urine constantly dribbles on to the abdominal skin leading to local infection and ammoniacal dermatitis. The urethra is not formed completely and its meatus is on the dorsal aspect. The exstrophy epispadias complex is caused by embryological defect in abdominal wall development and persistent cloacal membrane that prevents migration of the mesenchymal tissue toward the midline. Rupture of the cloacal membrane results in herniation of lower abdominal components to the wall and characteristic features.

Boys have a short flattened penis bent toward the dorsal aspect (chordee). In the female, the clitoris is bifid, the urethral opening is located dorsally between the clitoris and labia minora (epispadias) and the anus and vagina are anteriorly displaced. The pelvic pubic rami are widely separated and the umbilicus is displaced upward. Associated problems include inguinal hernia and undescended testes, anterior looking anus and rectal prolapse. Complications include VUR, urinary tract infections, small bladder capacity, urinary incontinence, bladder stones and genital and reproductive problems. Ultrasonography helps to detect renal anomalies and hydroureteronephrosis. It also assesses bladder capacity and postvoid residue following bladder closure. DTPA and DMSA scintigraphy, MCU and urodynamic studies are required.

The goals of reconstruction are closure of the bladder and urethra, closure of abdominal wall while ensuring preservation of kidneys, urinary continence, sexual function and improved appearance of genitalia. Staged repair involves closure of bladder and abdomen at 24–48 hours of life, epispadias repair (2–3 years) and bladder neck repair (4–5 years) with or without bladder augmentation.

POSTERIOR URETHRAL VALVES

Posterior urethral valves (PUV) are obstructing membranous folds within the lumen of posterior urethra. It is the most common cause of urinary tract obstruction in newborns as well as chronic kidney disease (CKD) due to urinary tract obstruction in children. PUV appear to develop at 9–14 weeks of gestation due to an obstructing persistent urogenital membrane that disrupts the normal embryologic development of the male urethra. Proposed alternative causes include overgrowth of urethrovaginal folds and abnormal integration of the Wolffian duct into the posterior urethra.

With widespread use of antenatal ultrasonography, PUV are increasingly detected prior to birth. In developing countries, patients present in the neonatal period or infancy with poor urinary stream, abdominal distension or respiratory distress due to lung hypoplasia. Often these symptoms are ignored and presentation delayed to late childhood with features of uremia. Many cases are suspected antenatally and the diagnosis confirmed on postnatal ultrasound and MCU **(Fig. 1)**.

Management

Fetal intervention for obstructive uropathy is associated with high risk of fetal and maternal morbidity without proven benefit for long-term renal outcome. Initial postnatal management includes stabilization of the patient, drainage of the urinary tract by placement of a catheter and confirmation of the diagnosis. Management includes correction of dyselectrolytemia, particularly hyperkalemia and interventions for respiratory distress and urosepsis. Renal function is monitored before, during bladder drainage, and after valve ablation.

Direct visualization of PUV by cystoscopy confirms the diagnosis. The decision to conduct primary ablation of valves, the preferred initial surgery, depends on birthweight, patient condition and caliber of the urethra to accommodate the cystoscope. A Fogarty catheter can be used under direct visual guidance of a neonatal cystoscope to ablate the valves even in preterm babies. If, primary valve ablation is not possible particularly in premature babies, a vesicostomy is done. Higher diversion with cutaneous loop ureterostomies are indicated with poor renal function and severely dilated and tortuous upper tracts that are unlikely to drain with vesicostomy or valve ablation.
Figure 1 Micturating cystourethrogram depicting gross vesicoureteric reflux in a patient with posterior urethral valves

Complications

About 33–50% of patients with PUV have secondary VUR. Chronic kidney disease is common in patients with PUV because of *in utero* renal dysplasia and/or acquired renal scarring due to infections or poor bladder function postoperatively. About 15–20% patients progress to end-stage renal disease. Bladder outlet obstruction results in muscular hypertrophy of the bladder wall with trabeculations, diverticula and collagen deposition. These changes lead to uninhibited bladder contractions (overactive bladder) and/or non-compliance that may persist despite relief of obstruction. Urodynamic findings demonstrate low capacity, poorly compliant bladders and high filling pressure.

Prognosis

All patients with PUV are at risk for developing CKD, and an initial creatinine of greater than 1 mg/dL at presentation and its persistent elevation after relief of urinary obstruction suggest increased risk for end-stage renal disease. A significant number of patients have persistent bladder dysfunction that requires clean intermittent catheterization and anticholinergic medications.

TESTICULAR MALDESCENT

An undescended testis is one that has remained high along its line of descent and has not reached the bottom of the scrotum. The incidence is 2.7–3% at birth in full term infants and decreases to 1% at 1 year of age. Undescended testes are common in premature infants, affecting 100% infants with gestational age of less than or equal to 32 weeks. An ectopic testis is one that has deviated from its path of descent, usually to the thigh, perineum, base of penis, or even the other side of the scrotum. The most common site is the superficial inguinal pouch. An ascending testis is one that had descended normally to the scrotum at birth, but ascends progressively to be located high in inguinal canal by childhood due to lack of elongation of the spermatic cord relative to body growth. Retractile testis refers to testis that having completed the descent process is not located in its normal scrotal position secondary to a hyperactive cremasteric reflex. Failure of testicular descent occurs because of insufficient gonadotropins and/or testosterone, dysgenetic testis or an anatomic abnormality (e.g., abnormal or malplaced gubernaculum, obstruction of inguinal canal or scrotum or short vas and/or vessels). Associated complications are:

1. *Infertility:* The higher temperature of the extrascrotal testis causes testicular dysplasia with poor development of seminiferous tubules and inadequate spermatogenesis.
2. *Trauma:* Testis located in the inguinal region is more prone to direct trauma.
3. *Torsion:* This is most likely in the postpubertal period when testicular size increases.
4. *Neoplasia:* The risk of malignancy is increased 10–20-fold on affected side and 7-fold on the contralateral side. The most common malignancy is a seminoma that develops in the second or third decade of life.
5. Hernia due to patent processus vaginalis.
6. Testicular atrophy.

Management

Since histological changes may be noted before 1 year of age, the best time for orchiopexy for inpalpable testes is by the age of 9 months. If the testis is palpable, one may wait for natural descent till the child is 12–15 months old. Early surgery carries higher risk of injury to the vessels and vas deferens (2–3%). Laparoscopy has 95% sensitivity for locating a testis or proving it absent and offers a reliable diagnostic and therapeutic option. A first stage

Fowler-Stephens' procedure is performed easily and effectively using a laparoscope; the second stage is done 6 months later.

Following orchiopexy, 2% cases recur and 2–5% show testicular atrophy. Fertility is preserved in 70–80% cases with unilateral and 40% after bilateral repair. The higher the location of the gonad, the greater is the risk of malignancy and infertility. Chances of fertility are minimal if orchiopexy is delayed beyond puberty in patients with bilateral maldescent.

PREPUTIAL ADHESION

At birth, the meatus should be visible at the glans even without preputial retraction. The natural separation of prepuce from the glans continues and is completed by 2-year of age. Preputial adhesion is present if the prepuce cannot be retracted fully beyond this age or balloons out on micturition. This adhesion, affecting 1–2% boys, is distinct from phimosis that refers to excessive tightness of the foreskin preventing its retraction behind the glans.

Most adhesions are mild and are usually managed by simple separation and retraction. The presence of epithelial debris at the coronal sulcus may cause irritation and infection. Forced retraction worsens the condition by producing tears in the foreskin that heal with scarring and contraction, leading to phimosis. Simple dilatation of the foreskin using aseptic precautions is useful in cases with pooling of urine and repeated attacks of balanoposthitis. Beyond the age of 2 years, adhesinolysis (stretching and forcibly separating the glans from the inner layer of prepuce) can be done as an outpatient procedure. Daily retraction and cleansing of the glans is essential during the subsequent 10–15 days to prevent recurrence. Following retraction the prepuce must be repositioned back on to the glans to avoid paraphimosis. Circumcision is recommended in cases with recurrent urinary infection, failure of adhesinolysis, in presence of balanitis xerotica and if the prepucial skin is scarred.

Hypospadias

Hypospadias refers to an abnormal ventral location of the urethral opening. The displaced urethral meatus may be located anywhere within the glans, shaft of penis, scrotum or perineum. With an incidence of 1 in 150 to 300 livebirths, it is among the most common congenital anomalies. Urethroplasty should be performed before school-going age. Most cases have acceptable cosmetic and functional outcome following repair.

ANTENATAL HYDRONEPHROSIS

Based on the criteria used, hydronephrosis is identified in 0.6–5.4% of pregnancies. However, the majority of cases (41–88%) resolve without sequelae, representing transient physiological obstruction or stasis. Other etiologies include PUJ obstruction, 10–30%, VUR, 10–20%, VUJ obstruction or megaureter (5–10%), duplex kidneys and/or ureterocele (2–7%), and PUV (1–2%). The Indian Society of Pediatric Nephrology (ISPN) recommends classifying antenatal and postnatal hydronephrosis using classification systems based on fetal renal pelvic APD and Society of Fetal Urology (SFU) grading systems, respectively **(Table 1 and Figs 2A to D)**. Antenatal management focuses on ultrasonographic monitoring for progression of hydronephrosis, detection of other extrarenal anomalies, signs of lower urinary tract obstruction (e.g., oligohydramnios, dilated thick-walled bladder, keyhole sign, urinoma) and/or loss of renal parenchyma (e.g., cortical thinning, poor corticomedullary differentiation, increased renal echogenicity, cysts). Pregnancy in fetuses with unilateral or bilateral ANH should proceed to term, except if complicated by severe oligohydramnios or major structural anomalies. Since antenatal diagnostic and therapeutic interventions have not

Table 1 Classification of antenatal hydronephrosis, based on renal pelvic anteroposterior diameter

	Renal pelvic anteroposterior diameter (APD)	
	Second trimester	*Third trimester*
Mild	4–6 mm	7–9 mm
Moderate	7–10 mm	10–15 mm
Severe	> 10 mm	> 15 mm

been demonstrated to impact long-term outcomes, these should be considered for fetuses with suspected lower urinary tract obstruction and oligohydramnios only at specialized centers.

While all infants with antenatal hydronephrosis should have postnatal ultrasound during the first week of life, ultrasonography is performed within 24–48 hours of birth in patients with suspected posterior urethral valves, oligohydramnios or severe bilateral hydronephrosis. Ultrasonography should evaluate for SFU grade **(Figs 2A to D)**, calyceal or ureteric dilation, cortical cysts, renal echogenicity and bladder wall abnormalities. Neonates with normal ultrasound examination in the first week of life should undergo a repeat study at 4–6 weeks. Infants with isolated mild unilateral or bilateral hydronephrosis (APD < 10 mm or SFU grade 1–2) should be followed by sequential ultrasound examinations alone as spontaneous resolution occurs by 2–5 years of age in most. Neonates with unilateral or bilateral hydronephrosis with renal pelvic APD greater than 10 mm, SFU grade 3–4 or ureteric dilatation should undergo an MCU at 4–6 weeks of life to detect VUR. If reflux is ruled out, a diuretic renal dynamic scan is done at 6–8 weeks to detect significant PUJ or VUJ obstruction. The differential function is estimated and renogram curve inspected for pattern of drainage. Surgery is indicated for obstructive drainage pattern associated with low or deteriorating differential function on renography, lower urinary tract obstruction, and VUR associated with recurrent UTI despite prophylaxis. Infants with VUR or severe PUJ obstruction should receive continuous antibiotic prophylaxis. Parents of these infants should receive counseling regarding risk of urinary infections and need for prompt management. **Flow chart 1** summarizes recommendations of the ISPN for postnatal evaluation and management of antenatally diagnosed hydronephrosis.

IN A NUTSHELL

1. Congenital anomalies of kidney and urinary tract constitute 20–30% of all anomalies identified in the prenatal period. Routine antenatal ultrasonography during pregnancy detects most anomalies.
2. All patients with antenatal hydronephrosis require postnatal evaluation by ultrasonography within the first week of life. Ultrasound is recommended within 24 hour of birth for infants with bilateral involvement, a solitary affected kidney or history of oligohydramnios.
3. Infants with suspected congenital anomalies of kidney and urinary tract should undergo renal function tests at end of first week of life.
4. All patients with congenital anomalies of kidney and urinary tract should receive regular follow-up for development of hypertension, proteinuria or renal dysfunction, anthropometry and evolution of underlying abnormality.

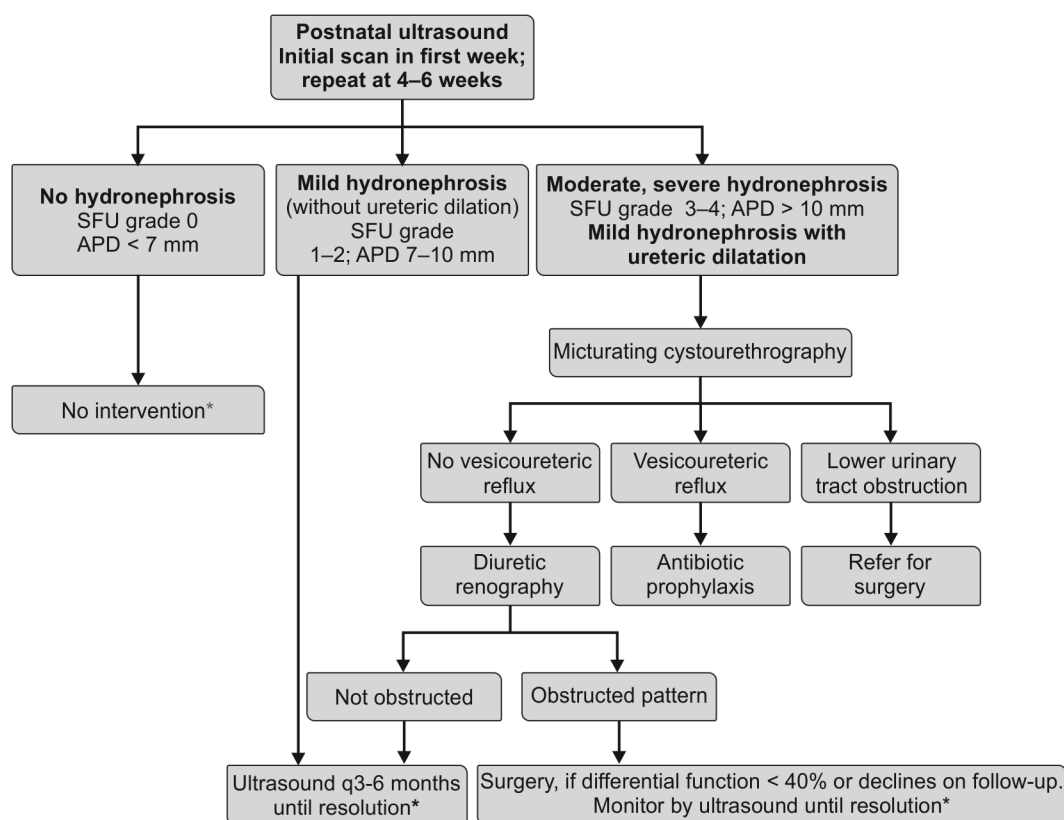
Flow chart 1 Postnatal evaluation in patients with antenatal hydronephrosis. Postnatal ultrasound is recommended at 3–7 days except if suspected lower urinary tract obstruction, when it is done earlier. Postnatal hydronephrosis is classified using Society of Fetal Urology grade or renal pelvic anteroposterior diameter (APD). Infants with normal findings should undergo a repeat study at 4–6 weeks. Patients with isolated mild hydronephrosis (unilateral or bilateral) should be followed with sequential ultrasounds, at 3- and 6-month, followed by 6–12 monthly until resolution; those with worsening hydronephrosis require closer evaluation. Patients with higher grades of hydronephrosis or dilated ureter(s) are screened for underlying obstruction or VUR. Diuretic renography is useful in detecting PUJ or VUJ obstruction and determining the need for surgery.


*Parents of infants with hydronephrosis should be counseled regarding the risk of urinary tract infections. [Reproduced with permission from Indian Pediatrics. 2013;50:215-31. Revised Guidelines on Management of Antenatal hydronephrosis].

Chapter 41.4
Cystic Kidney Diseases
Shina Menon

Renal cystic diseases comprise a group of sporadic and genetically determined congenital and acquired disorders characterized by the presence of cysts in one or both kidneys. For a clinician it is most beneficial to group them into genetic and nongenetic disorders **(Table 1)** as the approach to diagnosis and management is based on this.

PATHOGENESIS

Cysts, derived primarily from tubules, are epithelium-lined cavities filled with fluid or semisolid matter. Depending on the underlying disorder, cysts may develop in any part of the tubule between the Bowman's capsule and the tip of the renal papilla. There is no single mechanism for cyst formation, and it can be mediated by various inherited or acquired defects. The processes necessary for development and progression of renal cysts include proliferation of epithelial cells in segments of renal tubule, accumulation of fluid within this segment and irregularities in the organization of extracellular matrix.

AUTOSOMAL DOMINANT POLYCYSTIC KIDNEY DISEASE

Autosomal dominant polycystic kidney disease (ADPKD) is the most common inherited renal disorder with an estimated worldwide prevalence between 1:400 and 1:1,000. It affects all races, and the annual incidence of end-stage renal disease (ESRD) secondary to ADPKD is between 6 and 8.7 per million in United States and Europe. Data from India and other south Asian countries shows that 2–5% of all ESRD is attributed to ADPKD.

Genetics

It is inherited as an autosomal dominant trait with complete penetrance. About 5–10% of patients have no family history, suggesting a high spontaneous mutation rate. It is genetically heterogeneous with two known genes; *PKD1* on chromosome 16p13.3 causes 85% cases and *PKD2* on chromosome 4q21, around

Table 1 Classification of cystic kidney diseases

Genetic
Autosomal dominant
• Autosomal dominant polycystic kidney disease (ADPKD)
• Other systemic disorders: Tuberous sclerosis, von Hippel-Lindau disease
Autosomal recessive
• Autosomal recessive polycystic kidney disease (ARPKD)
• Juvenile nephronophthisis
Associated with multiple malformation syndromes
• Chromosome disorders: Trisomy 18
• Autosomal recessive: Bardet-Biedl syndrome, Meckel-Gruber syndrome, Jeune syndrome, Joubert syndrome
• X-linked syndromes: Orofacial digital syndrome
Nongenetic
• Multicystic dysplasia
• Medullary sponge kidney
• Simple renal cysts
• Hypokalemic cystic disease
• Acquired renal cystic kidney disease (in patients with chronic kidney disease)

15%. *PKD1* causes a more rapidly progressive form of the disease with earlier cyst formation and onset of ESRD at a mean age of 54 years. The mean age of ESRD onset with *PKD2* is 74 years.

Clinical Features

Autosomal dominant polycystic kidney disease is a systemic disorder with renal and extrarenal manifestations. The intrafamilial variability in the severity of manifestations suggests both genetic and environmental modifying factors. The cysts in ADPKD are distributed throughout the cortex and medulla, and most renal manifestations are related to their enlargement. Common symptoms are chronic flank pain, hematuria, infection, nephrolithiasis and hypertension. Some symptoms, especially pain, are proportionate to the kidney size, and patients may get some relief from cyst decompression. Hematuria can be microscopic or gross, secondary to cyst hemorrhage, infection or nephrolithiasis. Early in the course of the disease, impaired urinary concentrating ability and glomerular hyperfiltration is seen.

The most common extrarenal manifestation is hepatic cysts, which are rarely seen in children, and are noted more frequently with increasing age and declining renal function. Polycystic liver disease is usually asymptomatic, but symptoms may be seen due to mass effect from the enlarged cysts, or obstructive jaundice from bile duct compression. Cyst hemorrhage, infection, and rarely torsion may occur. Occasionally, cysts may be present in other organs like pancreas, seminal vesicles and arachnoid.

Intracranial aneurysms, usually asymptomatic, may be seen in 5–15% ADPKD patients. They may sometimes cause focal findings like cranial nerve palsy or seizure from compression of local structures. Rupture of an aneurysm may lead to subarachnoid hemorrhage and present with headaches, seizures and altered sensorium.

Diagnosis

The specific diagnosis of ADPKD requires an assessment of extrarenal manifestations, age at presentation, and family history. For patients presenting at a younger age, ultrasound screening of asymptomatic parents or grandparents may be required. Specific diagnostic criteria are based on the number of cysts and age at presentation.

Genetic testing by direct sequencing detects mutations in more than 90% of affected individuals. It can be used when the imaging results are equivocal and when a definite diagnosis is required in a younger individual, such as a potential living related kidney donor. Such testing is expensive, and is not available easily in developing countries.

Treatment

There is no known cure for ADPKD, and the current therapy is directed toward mitigating the complications of ADPKD and delaying the onset of ESRD. Hypertension, which can worsen renal function, and predispose the patient to intracranial hemorrhage, should be managed aggressively. ACE inhibitors or angiotensin receptor blockers may be preferred due to their effect on increasing renal blood flow, safety profile and renoprotective properties.

AUTOSOMAL RECESSIVE POLYCYSTIC KIDNEY DISEASE

Autosomal recessive polycystic kidney disease (ARPKD) is characterized by bilateral, symmetrically enlarged, poorly functioning kidneys in infants, and is associated with some degree of congenital hepatic fibrosis. It has a spectrum of severity, with the most severe forms presenting in the neonatal period. Occasionally it may present later in childhood. The incidence of ARPKD varies from 1 in 10,000 to 50,000 livebirths.

Genetics

It is transmitted as an autosomal recessive trait, and mutations in a single gene, *PKHD1* (chromosome 6p12) are responsible for the disease. *PKHD1* produces a protein called fibrocystin (or polyductin), whose disruption mediates cystogenesis through ciliary dysfunction in the renal epithelial cell.

Clinical Features

Autosomal recessive polycystic kidney disease is often noted antenatally with the affected fetus showing enlarged, echogenic kidneys with oligohydramnios. The fetus may have features of Potter sequence with characteristic facies, limb deformities and pulmonary hypoplasia. Up to half of the affected babies may not survive the neonatal period due to uremia or respiratory failure. Surviving children often have significant hypertension and chronic kidney disease (CKD), along with liver disease and portal hypertension secondary to congenital hepatic fibrosis, biliary ectasia and periportal fibrosis. A small group presents later with predominantly hepatic features or complications of portal hypertension.

Diagnosis

The diagnosis is suspected on antenatal ultrasound examination. The kidneys are enlarged with diffusely increased echogenicity, and there is associated oligohydramnios. It may sometimes appear similar to other renal cystic diseases. In such cases, the family history, evaluation of the liver for hepatic fibrosis, and absence of extrarenal malformations associated with other syndromes help to confirm the diagnosis.

Treatment

In the absence of specific therapy for ARPKD, the goals of management are early diagnosis and treatment of complications of hypertension, ESRD and portal hypertension. The prognosis of ARPKD for children who survive the first month of life has improved in recent years. Infants with massive kidneys resulting in respiratory and nutritional compromise may benefit from nephrectomy (unilateral or bilateral). For infants with ESRD, peritoneal dialysis is required until renal transplantation. Transplant outcomes in these patients are similar to those undergoing transplant secondary to other renal diseases. Older children may require surgical management of portal hypertension.

JUVENILE NEPHRONOPHTHISIS/MEDULLARY CYSTIC KIDNEY DISEASE COMPLEX

Juvenile nephronophthisis (NPH) and medullary cystic kidney disease (MCKD) comprise a group of diseases with similarities in renal morphology but variations in the modes of inheritance, age of onset and extrarenal manifestations.

Genetics

Nephronophthisis shows an autosomal recessive inheritance, presents in childhood, and progresses to ESRD before the age of 25. Multiple genes have been identified for various forms of NPH. Medullary cystic disease is caused by mutations in either the *MCKD1* or *MCKD2* genes and has an autosomal dominant mode of inheritance.

Clinical Features

Urinary concentrating defect leading to polydipsia and polyuria, along with significant salt wasting is one of the earliest manifestations. There is progressive renal failure with growth retardation, anemia and hypertension. The urine sediment is bland. Numerous extrarenal manifestations have been reported in association with NPH. Retinitis pigmentosa is the most common and the condition is referred to as renal retinal or Senior-Loken syndrome. NPH can also be a part of other syndromes like Bardet-Biedl syndrome (with obesity, mental retardation, polydactyly, retinitis pigmentosa, hypogenitalism), Cogan syndrome (with ocular apraxia) and Joubert syndrome (with coloboma and cerebellar ataxia). These associations are not seen with medullary cystic disease.

Diagnosis

Diagnosis of NPH is usually suspected in a child or adolescent with ESRD and extrarenal manifestations as described above. Ultrasound may show nonspecific findings of normal to small sized kidneys with loss of corticomedullary differentiation, increased parenchymal echogenicity and small cysts at the corticomedullary junction. Renal biopsy is usually not performed, but it may show irregular thickening and attenuation of tubular basement membrane, chronic tubulointerstitial nephritis and tubular atrophy.

Management

Management is supportive focusing on issues related to chronic kidney disease and need for renal replacement therapy.

OTHER CYSTIC KIDNEY DISORDERS

Medullary Sponge Kidney

Medullary sponge kidney (MSK) is characterized by nonprogressive dilatation of tubules and distal collecting ducts, associated with cysts and diverticula in the medullary pyramids. It usually occurs as a sporadic disorder, though it may be associated with other congenital anomalies, such as Beckwith-Wiedemann syndrome, Ehlers-Danlos syndrome, anodontia and Caroli disease. It is often asymptomatic, and may remain undetected. Some patients may present with renal colic, hematuria, urinary tract infections and nephrolithiasis. Up to 50% of the patients have hypercalciuria, which along with urinary stagnation in the dilated tubules and incomplete distal renal tubular acidosis may predispose to stone formation.

The diagnosis of MSK is confirmed on intravenous pyelography, which shows enlarged kidneys, characteristic brush-like linear striations, papillary contrast blush and persistent medullary opacification. Management of MSK involves management of nephrolithiasis and urinary infections. When managed and followed up appropriately, MSK does not lead to renal insufficiency.

Multicystic Dysplastic Kidney

Multicystic dysplastic kidney (MCDK) is a developmental anomaly resulting in multiple cysts of varying sizes, without identifiable normal renal parenchyma. It is believed to be a result of severe obstructive hydronephrosis secondary to atresia of the ureter or renal pelvis. It is proposed that MCDK results from abnormal interaction between the ureteric bud and metanephric mesenchyme. The affected kidney is nonfunctional, with the contralateral kidney working normally and showing compensatory hypertrophy. It is one of the most common causes of an abdominal mass in a newborn.

Multicystic dysplastic kidney is often diagnosed on prenatal ultrasonography or may sometimes be diagnosed incidentally on an ultrasound done for unrelated reasons. The contralateral system is abnormal in one-third patients with anomalies like ureteropelvic junction obstruction and vesicoureteral reflux. Voiding cysto-

urethrogram and a radioisotope scan are recommended as part of the work-up, particularly if the contralateral kidney is abnormal on the ultrasound.

Multicystic dysplastic kidney has a benign course and the incidence of complications is extremely rare. Almost half undergo spontaneous involution. While there are anecdotal case reports, large series data indicate that MCDK is not associated with an increased risk for hypertension or neoplasm.

Simple Cysts

Simple cysts are rare in children and are usually detected as an incidental finding on an ultrasound. They may be single or multiple, but their characteristic feature is the presence of smooth walls with no internal echoes. Rarely, they may cause hematuria or flank pain.

Acquired Cystic Kidney Disease

Acquired cystic kidney disease is characterized by presence of multiple small cysts in the renal cortex and medulla of patients with ESRD, unrelated to inherited renal cystic diseases. Acquired cysts are found in 10–20% of patients with CKD, and the prevalence increases with the duration of dialysis. Acquired renal cysts are also seen with chronic hypokalemia.

It is important to have a systematic approach to patients with cystic disease. A detailed family history (including ultrasonography of family members occasionally), presence of consanguinity and a pedigree chart help to determine if there is a familial basis and what the mode of inheritance is likely to be. Clues to diagnosis may be obtained from the patient age, renal function and presence of extrarenal manifestations. Further investigations are planned based on initial assessment.

IN A NUTSHELL

1. It is important to have a systematic approach to patients with cystic disease. Family history (including a pedigree chart) and presence of extrarenal manifestations provide important clues toward diagnosis.
2. Not all genetic disorders have their onset at birth, and not all congenital disorders are heritable.
3. Autosomal dominant polycystic kidney disease usually presents after the age of 30 years, but may present earlier also. It presents with hematuria, flank pain, and hypertension.
4. Autosomal recessive polycystic kidney disease presents in utero or in early infancy, though milder cases can present later in childhood. The kidneys are usually large and uniformly hyperechoic. Discrete cysts may not be visible.

Chapter 41.5
Hematuria
Rajiv Sinha

Hematuria can be either gross (macroscopic) when it can be appreciated by naked eye or microscopic when red blood cells (RBC) are detected only on urine microscopy. The color of urine helps to determine the site of disease, with cola or tea color seen usually with glomerular disease, and pink or frank red color suggesting a nonglomerular cause. Microscopic hematuria is the presence of more than 5 RBC per high power field (HPF) in a centrifuged sample. Persistent hematuria is defined as the presence of microscopic hematuria in more than two samples collected over the next 2–3 weeks.

EPIDEMIOLOGY

Macroscopic hematuria has an estimated incidence of 1.3 per 1,000 children. The incidence of microscopic hematuria varies with definition. Screening programs in school children have reported persistent microscopic hematuria in 1–2% of children. The prevalence fall when the number of samples and follow-up duration are increased; 0.41% when four samples were collected and 0.14–0.32% when five specimens were analyzed.

DETECTION OF HEMATURIA

Although red urine suggests gross hematuria, it needs to be confirmed on urinalysis to differentiate from other causes **(Table 1)**. Microscopic hematuria is detected only by urinalysis including urine dipstick and microscopy. Urinary dipsticks for hemoglobin are based on oxidation of *ortho*-toluidine by organic peroxide in presence of hemoglobin that serves as a catalyst. The product of the reaction has a blue color, the intensity of which is matched against a color chart. The test can detect as little as 150 μg/L of free hemoglobin, with 100% sensitivity and 99% specificity in detecting 1–5 RBC per HPF. Since myoglobin/hemoglobin can also catalyze this oxidation process, the absence of RBC on urine microscopy in a patient with positive urine dipstick suggests myoglobinuria or hemoglobinuria. Reducing agents such as vitamin C can give false negative results. False positive results can occur if the urine sample is concentrated or following contamination with oxidizing agents such as povidone iodine or hypochlorite. RBCs are identified by their biconcave disc appearance. False negative results can occur if the urine is diluted or if urine pH is alkaline, leading to RBC lysis.

ETIOLOGY

History, examination and urinalysis help to distinguish between glomerular and nonglomerular causes of hematuria **(Table 2)**.

Table 2 Etiology of hematuria

Glomerular	Nonglomerular
Glomerulonephritis (GN)	Urinary tract infection
Postinfectious GN	Hypercalciuria
Membranoproliferative GN*	Renal calculi*
Membranous nephropathy	Hydronephrosis (rare)
IgA nephropathy*	Trauma; exercise
Systemic lupus erythematosus	Renal vein thrombosis
Henoch-Schönlein purpura	Chemical cystitis, e.g., cyclophosphamide
Wegener granulomatosis; renal vasculitis	Interstitial nephritis
Hemolytic uremic syndrome	Coagulopathy
Alport syndrome*	Vascular malformations*
Cystic renal disease*	Nutcracker syndrome*
Familial hematuria (thin basement membrane disease)*	Tuberculosis* Wilms tumor; rhabdomyosarcoma
Nonfamilial benign hematuria	False: Menstruation; factitious

* Recurrent hematuria

Glomerular hematuria is likely if RBC casts are present and/or more than 20–30% of RBCs are dysmorphic (more easily identified under phase contrast microscope). Systemic manifestations like fever, pharyngitis, edema, rash and arthritis are more commonly associated with glomerular disease. The most common causes of gross hematuria are renal calculi and IgA nephropathy; however, postinfectious glomerulonephritis remains an important etiology among children from developing regions. Thin basement membrane nephropathy is the most common cause of persistent asymptomatic microscopic hematuria.

EVALUATION OF A CHILD WITH HEMATURIA

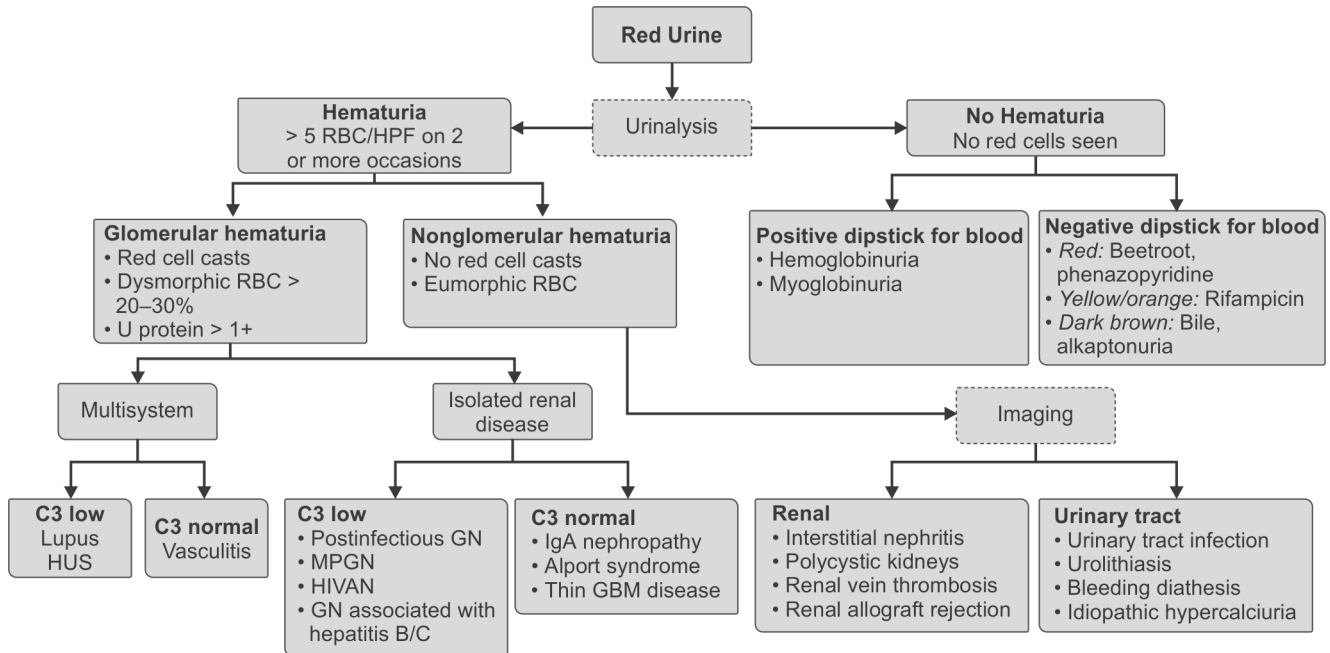
The emphasis of evaluation is on identifying common and treatable causes while avoiding unnecessary expensive and invasive interventions where the etiology is more likely to be benign. Significant family history, findings like colic, painful micturition, rash or joint pains, and the presence of hypertension, significant proteinuria and/or azotemia are considered as *red flag signs* and these patients are evaluated in greater detail. Children with hematuria can present in the following ways: (i) gross hematuria (red or dark-colored urine); (ii) microscopic hematuria in a symptomatic child; and (iii) an asymptomatic child with incidental finding of microscopic hematuria. A stepwise approach **(Flow chart 1)** helps to identify important etiologies while avoiding unnecessary evaluation.

Gross Hematuria

The first step is to confirm the presence of *true* hematuria on urine microscopy. Urinalysis also helps to distinguish between

Table 1 Causes of urinary discoloration

Color	Pathologic causes	Foods and drugs
Cloudy	Phosphaturia, pyuria, chyluria, lipiduria, hyperoxaluria	Diet high in purine-rich foods (hyperuricosuria)
Brown	Bile pigments, myoglobin	Fava beans; levodopa, metronidazole, nitrofurantoin
Brownish black	Bile pigments, melanin, methemoglobin, alkaptonuria, homogentisic acid	Levodopa, methyldopa, senna
Green, blue	Urinary infection with *Pseudomonas*, biliverdin	Amitriptyline, IV cimetidine, promethazine, indigo, methylene blue, triamterene
Red	Hematuria, hemoglobinuria, myoglobinuria, porphyria	Beets, blackberries, rhubarb; phenolphthalein, rifampicin
Dark yellow, orange	Concentrated urine	Carrots, rifampicin

Flow chart 1 Workup for a patient with red colored urine


Abbreviations: MPGN, membranoproliferative glomerulonephritis; HIVAN, HIV-associated nephropathy; GBM, glomerular basement membrane; HUS, hemolytic uremic syndrome.

glomerular or nonglomerular etiology **(Flow chart 1)**. Although gross hematuria may be associated with up to 2+ proteinuria, 3–4+ proteinuria signifies glomerular origin. The presence of edema or hypertension with or without azotemia suggests glomerulonephritis and the investigations should be directed toward identifying the etiology **(Flow chart 1)**. Low levels of complement C3 are commonly associated with postinfectious glomerulonephritis, but are also associated with lupus nephritis, membranoproliferative glomerulonephritis and atypical hemolytic-uremic syndrome. The presence of low levels of C4 as well as C3 suggests lupus, confirmed by testing for antinuclear antibodies. Levels of C3 return to baseline within 8–12 weeks of postinfectious glomerulonephritis; failure of C3 to normalize by 12 weeks suggests an alternate etiology and need for renal biopsy **(Box 1)**. Progressive rise in serum creatinine along with other features of glomerulonephritis suggests rapidly proliferative glomerulonephritis. Renal biopsy is essential to ascertain the diagnosis and plan specific management. Wegener granulomatosis (granulomatous polyangiitis) and other forms of pauci-immune crescentic glomerulonephritis should be considered in presence of normal complement C3 and presentation as rapidly progressive glomerulonephritis; testing for antinuclear cytoplasmic antibody (ANCA) helps confirm the diagnosis.

Dysuria, flank pain and colic are usually associated with nonglomerular etiologies such as urinary tract infection and nephrolithiasis. Other than bacterial infections, certain viruses, e.g., adenoviruses, may cause cystitis associated with gross hematuria. Patients with hypercalciuria may present with gross hematuria. The diagnosis of sickle cell hemoglobinopathy and schistosomiasis should be considered in susceptible populations. Wilms tumor may present with painless gross hematuria, while patients with rhabdomyosarcoma of the bladder often have painful voiding or other symptoms along with macroscopic hematuria. The diagnosis of these conditions is aided by a careful abdominal ultrasound. Patients with history of abdominal trauma may require CT in order to find a renal or urological lesion.

Nutcracker syndrome should be considered in children with recurrent isolated gross hematuria without an obvious cause. Compression of the left renal vein between the aorta and superior mesenteric artery resulting in left renal vein entrapment and hypertension is postulated to cause the intermittent gross or microscopic hematuria. The diagnosis is suggested by Doppler ultrasonography and/or MR angiography. Exercise induced hematuria refers to transient hematuria occurring immediately after severe exercise and is thought to be caused by RBC excretion secondary to a hyperdynamic circulation induced by the exercise. Cystoscopy should be considered in cases with persistent gross hematuria of suspected nonglomerular etiology, where routine investigations fail to provide a diagnosis.

Microscopic Hematuria with or without Symptoms

Approach to a child with microscopic hematuria and other symptoms are similar to that suggested for patients with gross hematuria. However, asymptomatic microscopic hematuria and/

BOX 1 Indications for renal biopsy in hematuria

- Significant proteinuria (except with postinfectious glomerulonephritis)
- Persistently (> 12 weeks) low serum complement C3
- Signs of systemic disease, e.g., systemic lupus erythematosus, Henoch-Schönlein purpura, ANCA (antineutrophil cytoplasmic antibody) positive vasculitis
- Family history suggestive of Alport syndrome
- Recurrent gross hematuria of unknown etiology
- Persistent microscopic glomerular hematuria and parental anxiety about diagnosis and prognosis*.

*Renal biopsy is usually not done in cases with isolated microscopic hematuria (i.e., without proteinuria or systemic manifestations).

or mild proteinuria are known to occur transiently during febrile illness or after rigorous exercise. Hence, unnecessary investigations may be avoided in patients with asymptomatic microscopic hematuria without proteinuria, emphasizing on careful follow-up on the long-term.

Quigley R. Evaluation of hematuria and proteinuria: how should a pediatrician proceed? Curr Opin Pediatr. 2008;20(2):140-4.

IN A NUTSHELL

1. A stepwise approach to evaluation of hematuria prevents unnecessary investigations, while decreasing the chance of missing important etiologies.
2. It is important to differentiate between glomerular and non-glomerular hematuria.
3. Ultrasound helps to rule out structural pathologies, such as obstruction, tumor and calculi.
4. Symptomatic patients with features of glomerulonephritis require detailed evaluation, including biopsy.
5. Patients with family history of hematuria require evaluation to exclude Alport syndrome and thin basement membrane disease.
6. Children with asymptomatic isolated microscopic hematuria without proteinuria are followed in a wait and watch manner without intensive investigations.

Chapter 41.6
Glomerulonephritis

ACUTE NEPHRITIC SYNDROME

Amarjeet Mehta

Nephritic syndrome is a clinical syndrome characterized by hematuria, proteinuria, edema, hypertension and impaired renal function. The underlying mechanism is glomerular injury with inflammation. In developing countries, postinfectious glomerulonephritis (GN), with an incidence of 2/100,000 person-years, accounts for 50–90% cases of nephritic syndrome in children; the incidence is much lower at 0.3/100,000 person-years in developed regions. Other etiologies of nephritic syndrome are listed in **Box 1**.

PATHOGENESIS

The hallmark of acute GN is generalized glomerular inflammation with proliferation of resident glomerular cells and infiltration by lymphocytes or neutrophils. Glomerular inflammation results from antigen-antibody reactions, which begin with antibodies binding directly or to an antigen trapped or expressed in the glomerulus, leading to activation of one or more systems of inflammatory mediators, e.g., the complement cascade, coagulation factors, cytokines or growth factors that cause glomerular injury. In most conditions, humoral as well as cellular immune responses are involved.

The pathologic correlate of acute nephritic syndrome is proliferative GN. Proliferation is initiated by neutrophils and monocytes but is caused chiefly by an increase in resident glomerular endothelial and mesangial cells. This inflammation is termed diffuse proliferative GN when it involves most of the glomeruli; less extensive involvement is termed focal prolifera-tive GN **(Fig. 1A)**. Renal biopsy shows diffuse endocapillary proliferative GN with numerous polymorphonuclear cells and

- **Crescentic glomerulonephritis:* Immune complex, pauci-immune, antiglomerular basement membrane disease
- Cryoglobulinemia.

*Typically present as rapidly progressive glomerulonephritis.

---

presence of humps on external (subepithelial) side of glomerular basement membrane **(Fig. 1B)**. Immunofluorescence examination shows granular deposits of complement C3, immunoglobulin (Ig) G, and rarely, IgM and IgA. Positivity for IgG, IgA, IgM, C3, C4 and C1q, termed *full house* staining, suggests lupus nephritis. The inflammation and expansion leads to enlargement of glomeruli resulting in impaired circulation, reduced glomerular filtration rate (GFR) and retention of salt and water, fluid overload and hypertension with or without encephalopathy and pulmonary edema.

CLINICAL FEATURES

Acute postinfectious GN usually follows an upper respiratory or skin infection with a nephritogenic strain of group A β-hemolytic *Streptococcus*, with latency of 1–2 weeks and 2–6 weeks, respectively. Recent history of sore throat or skin infection, increased antistreptolysin O (ASO) and/or anti-DNAse antibody titer and marked but transient reduction in C3 and C4 levels suggest acute poststreptococcal GN. A similar presentation may be noted in membranoproliferative glomerulonephritis (MPGN), IgA nephropathy, Henoch-Schönlein purpura and systemic lupus erythematosus (SLE). These entities are differentiated by clinical, laboratory and histological features.

Patients present with hematuria, facial edema and oliguria. The urine is described as dark, cola or tea colored, smoky or dirty. Headache, malaise and anorexia may be associated. The course of illness in patients with the acute nephritic syndrome might be complicated by severe hypertension, cardiac failure and pulmonary edema. Posterior reversible encephalopathy syndrome manifests with visual alterations, mental disturbances, severe headache and seizures; characteristic changes are seen on MRI. Patients with the acute nephritic syndrome should be distinguished from rapidly progressive glomerulonephritis (RPGN), characterized by features of the nephritic syndrome followed by rapid decline of renal function over days to weeks. These patients need prompt evaluation and therapy.

EVALUATION

Careful urinalysis is the most important investigation **(Box 2)**. The presence of red blood cells and red cell casts is characteristic. The detection of few leukocytes is not uncommon and indicates glomerular inflammation. Mild proteinuria is almost always present; nephrotic range proteinuria is uncommon. Mild anemia is frequently noted and is dilutional. Renal functions are mildly deranged or normal. Mild hypoalbuminemia may be present, but serum albumin values below 2.5 g/dL are unusual. Low levels of C3 are seen in patients with postinfectious GN, MPGN and lupus nephritis. Transient decrease in C4 levels is seen in lupus and in some patients with MPGN.

Kidney biopsy is recommended in patients with extrarenal symptoms, renal failure lasting more than 7–10 days, persistent nephrotic range proteinuria, low C3 that persists for more than 12 weeks and hematuria that does not resolve in 6 months.

BOX 2 Evaluation of acute nephritic syndrome

Initial evaluation
- Blood counts, urea, creatinine, electrolytes, albumin
- Urinalysis: Microscopy; spot urine protein: creatinine ratio; 24 hours urinary protein
- Throat culture or culture of skin lesions
- Antistreptococcal antibody titer: Antistreptolysin O, anti-DNAse B, antihyaluronidase
- Complement C3, C4

Subsequent evaluation
- Antinuclear antibody (ANA); other autoantibodies if ANA is positive
- Antineutrophil cytoplasmic antibody
- Anti-GBM antibody titer (if pulmonary involvement)
- Renal biopsy (if atypical features).

Abbreviation: anti-GBM, antiglomerular basement membrane.

TREATMENT

Most patients have subclinical disease or mild symptoms that can be managed at home or on outpatient basis. Patients with acute and severe manifestations should be hospitalized. Bed rest and restriction of fluid and sodium intake are advised. Loop diuretics [furosemide 2 mg/kg intravenously (IV) or oral, divided in two doses] are used in presence of significant edema, hypertension and/or pulmonary edema. Thiazide diuretics are usually ineffective. Prompt medical management is required for hyperkalemia, pulmonary edema and congestive heart failure.

Patients with severe hypertension require antihypertensive treatment. Nifedipine (0.5 mg/kg q6h) or hydralazine (0.1 mg/kg IV) is effective but may cause tachycardia. Angiotensin converting enzyme (ACE) inhibitors and angiotensin receptor blockers are avoided due to risks of reduction in GFR and hyperkalemia. Sodium nitroprusside is effective in severe hypertension with encephalopathy. Renal replacement therapy, as hemodialysis or peritoneal dialysis, is indicated in patients with hyperkalemia, acid base imbalance, fluid overload and uremia not responding to drug therapy alone. While therapy with immunosuppressive agents is not required in patients with postinfectious GN, corticosteroids and/or other agents have been used in patients with IgA nephropathy, vasculitis and lupus nephritis. Patients with persistent proteinuria benefit from treatment with ACE inhibitors.

IN A NUTSHELL

1. Nephritic syndrome is a clinical syndrome of hematuria, proteinuria, edema, often with hypertension and a mild degree of acute kidney injury.
2. The pathologic correlate of acute nephritic syndrome is proliferative GN and its chief cause is acute postinfectious GN.
3. Hypertensive encephalopathy, hyperkalemia, pulmonary edema and uremia are uncommon but life-threatening complications.
4. Management is supportive, comprising loop diuretics, anti-hypertensive agents, fluid and salt restriction, and dialysis as required. The role of immunosuppression is limited.

RAPIDLY PROGRESSIVE GLOMERULONEPHRITIS

Arvind Bagga, Shina Menon

Rapidly progressive glomerulonephritis is characterized by acute GN with rapid loss of renal function (more than 50% decrease in GFR over days to weeks). Histology shows the presence of crescents (crescentic GN) involving 50% or more glomeruli. This may be seen in a variety of conditions including poststreptococcal GN, renal vasculitis, IgA nephropathy, SLE and MPGN **(Box 3)**.

EPIDEMIOLOGY

The exact incidence of RPGN in children is not known. Crescentic GN comprises about 5% of unselected renal biopsies in children. Immune complex GN is the most common pattern of crescentic GN in children accounting for 75–80% of cases in most reports. Pauci-immune crescentic GN, while common in adults, is less frequent in children, accounting for 15–20% cases. Recent studies show decline in proportion of patients with immune complex GN and increasing number with pauci-immune crescentic GN.

ETIOLOGY

Based on pathology and immunofluorescence staining patterns, crescentic GN is classified into the following categories.
- *Immune-complex GN* It is a heterogeneous group characterized by proliferative GN with crescents secondary to multiple stimuli, and granular deposits of Ig and complement along capillary walls and in the mesangium on immunofluorescence. The causes include infections, systemic diseases and pre-existing primary GN **(Box 3)**.
- *Pauci-immune GN* It includes renal-limited vasculitis, and the renal manifestations of microscopic polyangiitis, granulomatosis with polyangiitis (formerly Wegener's granulo-

---

BOX 3 Causes of rapidly progressive glomerulonephritis (RPGN)

Immune Complex GN

Postinfectious GN: Poststreptococcal nephritis, infective endocarditis, shunt nephritis, other bacterial infections, human immunodeficiency virus, hepatitis B and C, syphilis

Systemic disease: Systemic lupus erythematosus, Henoch-Schönlein purpura, mixed connective tissue disorder, juvenile idiopathic arthritis

Primary GN: IgA nephropathy, membranoproliferative glomerulonephritis, membranous nephropathy

Pauci-immune Crescentic GN

Microscopic polyangiitis, granulomatosis with polyangiitis (Wegener's granulomatosis), renal limited vasculitis, eosinophilic granulomatosis with polyangiitis (Churg-Strauss disease)

Idiopathic crescentic GN

Abbreviation: GN, glomerulonephritis.

matosis), or eosinophilic granulomatosis with polyangiitis (formerly Churg-Strauss syndrome). They show few or no immune deposits on immunofluorescence. Majority of the patients have antineutrophil cytoplasmic autoantibodies (ANCA) in blood, and are collectively classified as ANCA-associated vasculitides. Approximately 10–30% of patients with pauci-immune crescentic GN are ANCA negative. These patients have fewer constitutional and extrarenal symptoms than those who are ANCA-positive.

- *Antiglomerular basement membrane (GBM) GN:* It is uncommon in childhood. It is caused by an autoantibody directed against the α3 chain of type IV collagen. Pulmonary involvement (Goodpasture syndrome) is rare. Approximately, 5% patients with Alport syndrome who have undergone a renal transplant may develop anti-GBM GN in the first year of transplant.

CLINICAL FEATURES

The typical presentation is with a nephritic syndrome that fails to resolve and presents with persistent macroscopic or microscopic hematuria, oliguria, hypertension and edema. Fluid overload and renal dysfunction may lead to hypertensive emergencies, pulmonary edema and cardiac failure. Patients with pauci-immune RPGN may have systemic symptoms at onset involving the respiratory tract (cough, sinusitis), skin (vasculitic rash), musculoskeletal (joint pain, swelling), and nervous system (seizures, altered sensorium). Those with anti-GBM GN present with hemoptysis and occasionally pulmonary hemorrhage.

INVESTIGATIONS

Rapidly progressive glomerulonephritis is a medical emergency, and a delay in instituting treatment can lead to irreversible loss of renal function. It is important to follow a rational approach towards diagnosis and management especially in resource-limited settings. The diagnosis of the etiology depends on integrating clinical data with serology and renal histology. Urinalysis shows microscopic hematuria, characterized by dysmorphic red cells and red cell casts in all patients, along with a variable degree of proteinuria (2+ to 4+), and leukocyte, granular and tubular epithelial cell casts. Renal insufficiency is usually present at diagnosis.

Serological investigations are important in evaluating the etiology and for monitoring disease activity. Total hemolytic complement and C3 are reduced in postinfectious GN, SLE and MPGN. Patients with SLE and type 1 MPGN also have low C1 and C4 due to activation of the classic complement pathway. Antinuclear antibody (ANA) and antidouble stranded DNA autoantibodies are seen in patients with SLE. ANCA is elevated in most patients with pauci-immune crescentic GN. It should be screened by indirect immunofluorescence for the staining pattern and by enzyme-linked immunosorbent assay (ELISA) for proteinase-3 (PR3) and myeloperoxidase (MPO). Granulomatosis with polyangiitis is associated with PR3 ANCA, which produces a cytoplasmic pattern (c-ANCA). MPO ANCA, with perinuclear staining (p-ANCA), is seen in renal limited vasculitis and drug-induced crescentic GN. Patients with microscopic polyangiitis have equal distribution of both types of ANCA. 10% of patients with granulomatosis with polyangiitis or microscopic polyangiitis have negative assays for ANCA. Anti-GBM IgG antibodies are seen in anti-GBM nephritis or Goodpasture syndrome and correlate with disease activity.

HISTOPATHOLOGY

Crescents may be completely cellular or may show variable scarring and fibrosis. Cellular crescents are characterized by proliferation of macrophages, epithelial cells and neutrophils, and in fibrous crescents, the cells are replaced by collagen **(Fig. 1C)**. Fibrocellular crescents show a mixture of both features. Interstitial changes range from acute inflammatory infiltrate to chronic interstitial scarring and tubular atrophy. The presence, location and nature of immune deposits on immunohistology and electron microscopy help diagnose the etiology of RPGN. *Full house* deposits of granular IgG, IgA, IgM, C3, C4 and C1q are seen in SLE; other immune complex GNs have similar characteristic deposits. Patients with vasculitis, both with and without ANCA positivity, have few or no immune deposits. Anti-GBM disease is characterized by linear deposits of IgG and C3.

MANAGEMENT

There are two components of treatment of RPGN: (1) *induction* of remission and (2) *maintenance* **(Box 4)**. Standard induction therapy includes high-dose steroids and cyclophosphamide, with additional therapy for those with life or organ-threatening disease. Both IV and oral cyclophosphamide have been used. IV therapy is more likely to induce remission and has a lower risk of infection and leukopenia. Evidence for use of other agents like rituximab, mycophenolate mofetil (MMF) and IV Ig is limited. Plasmapheresis or plasma exchange may be beneficial for patients with RPGN due to lupus, Henoch-Schönlein purpura and severe proliferative GN, and in life-threatening pulmonary hemorrhage.

The duration of maintenance therapy in crescentic GN depends on the underlying disease. Most patients with ANCA-associated disease need long-term maintenance immunosuppression due to the risk of relapses. Azathioprine is preferred over extended treatment with cyclophosphamide due to significant risks associated with the latter. MMF may also be used as an alternative for maintenance therapy in patients who have ANCA vasculitis, and who are allergic to or intolerant of azathioprine.

OUTCOME

Patients with poststreptococcal crescentic GN have a satisfactory prognosis, with most showing spontaneous improvement. Patients with pauci-immune crescentic GN, MPGN and idiopathic RPGN have less favorable outcomes than Henoch-Schönlein purpura or systemic lupus. End-stage renal disease (ESRD) may occur in the long-term in up to 25% patients with ANCA-associated vasculitis. The outcome is determined by the severity of renal

---

BOX 4   Treatment of crescentic glomerulonephritis

Induction

Methylprednisolone 15–20 mg/kg (maximum 1g) IV daily for 3–6 doses

Prednisolone 1.5–2 mg/kg/day PO for 4 weeks; taper to 0.5 mg/kg daily by 3 months followed by 0.5–1 mg/kg on alternate day

*Cyclophosphamide 500–750 mg/m^2 IV every 3–4 weeks for 6 pulses

#Plasma exchange

Maintenance

Azathioprine 1.5–2 mg/kg/day for 12–18 months

Alternate day low-dose prednisolone

Consider mycophenolate mofetil (1,000–1,200 mg/m^2/day) or cyclosporine if disease activity is not controlled with azathioprine or if does not tolerate azathioprine

Agents for refractory disease

Intravenous immunoglobulin, TNF-α antibody (infliximab), rituximab.

*Dose reduction is necessary in patients showing impaired renal function.
#Early plasma exchange is recommended for patients who are dialysis dependent at presentation or biopsy shows severe histological changes (> 50% crescents).
Abbreviation: TNF, tumor necrosis factor.

failure at presentation, promptness of intervention and underlying diagnosis. The potential for recovery corresponds with the relative proportion of cellular or fibrous components in the crescents, and extent of tubulointerstitial scarring and fibrosis.

IN A NUTSHELL

1. Rapidly progressive glomerulonephritis is an acute illness with rapid loss of renal function over days to weeks, characterized histologically by crescentic GN.
2. Prompt diagnosis and early treatment is essential to ensure renal recovery.
3. Treatment strategies should be individualized for patients using standard guidelines.

IMMUNOGLOBULIN A NEPHROPATHY

Manisha Sahay

Immunoglobulin A (IgA) nephropathy is a common GN with peak incidence in the 2nd and 3rd decades of life. Certain bacterial and viral infections are implicated in the pathogenesis of IgA deposition but the evidence is inconclusive. Genetic factors are suggested to play a role in causation and progression of disease; in some cases the illness is transmitted as an autosomal dominant trait with incomplete penetrance.

The IgA nephropathy is associated with mesangial deposition of predominantly polymeric IgA1. This subclass of IgA carries distinctive O-linked sugars at its hinge region, is chiefly produced in the bone marrow and cleared by liver through sialoglycoprotein receptors and Kupffer cell Fcα receptors. The other subclass, IgA2 has no hinge, does not carry sugars and is chiefly derived from the gastrointestinal and respiratory tract mucosa. Circulating IgA1 in IgA nephropathy has abnormal O-linked hinge region sugars with reduced galactosylation, and is not cleared by the liver. Some patients show increased serum levels of IgA and circulating macromolecular IgA, IgA immune complexes and IgA rheumatoid factor. Mesangial deposition of polymeric IgA1 leads to mesangioproliferative GN. Some patients show activation of the alternate complement pathway with C3 and properdin deposition.

CLINICAL FEATURES

Over one-half of children present with one or recurrent episodes of gross hematuria following upper respiratory infection (synpharyngitic hematuria); some have incidentally detected microscopic hematuria and mild proteinuria. Less than 10% present with nephrotic syndrome or RPGN with edema, hypertension, renal insufficiency and hematuria. Patients with rheumatic diseases, dermatitis herpetiformis, cirrhosis, celiac disease, human immunodeficiency virus (HIV), sarcoidosis and malignancy may also show glomerular deposits of IgA.

DIAGNOSIS

The diagnosis of IgA nephropathy is made on kidney biopsy, performed chiefly for persistent microscopic hematuria and proteinuria, nephrotic syndrome or RPGN. Light microscopy shows focal or diffuse mesangial proliferation and matrix expansion. Segmental crescents and/or necrosis are noted in children with deteriorating renal function. The presence of glomerulosclerosis indicates chronicity. The Oxford histological classification incorporates scores for mesangial hypercellularity, endocapillary proliferation, segmental glomerulosclerosis, and tubular atrophy and interstitial fibrosis. Immunofluorescence shows prominent deposits of IgA with or without C3 and IgG in the mesangium and glomerular capillary wall. This IgA is predominantly J chain containing polymeric IgA1; however, mesangial secretory IgA2 may be seen **(Fig. 1D)**. Electron microscopy reveals electron-dense deposits in mesangium, subendothelial and subepithelial spaces.

MANAGEMENT

Patients with biopsy proven IgA nephropathy should be screened for disorders associated with IgA deposits. General interventions consist of measures to slow progression of renal disease, including management of hypertension and proteinuria. ACE inhibitors and angiotensin receptor blockers are preferred because of antiproteinuric and antihypertensive effects **(Box 5)**. The role of fish oil is controversial. Patients with persistent proteinuria despite ACE inhibition and those presenting with nephrotic syndrome may benefit from additional therapy with prednisolone (0.5–1.0 mg/kg/day for 6–12 months). Those with RPGN benefit from combined therapy with IV methylprednisolone 15 mg/kg/day for 3 days, and cyclophosphamide 500 mg/m^2 IV q3–4 weeks for six doses; these patients require prolonged maintenance therapy as for crescentic
Figures 1A to D (A) Postinfectious glomerulonephritis (GN), showing hypercellular glomerulus with diffuse endocapillary proliferation and infiltration by polymorphonuclear cells; (B) Poststreptococcal GN. Electron microscopy showing a subepithelial electron-dense deposit; (C) Crescentic GN. Note the large circumferential cellular crescent occupying the whole Bowman space. The glomerulus is compressed and shifted; (D) IgA nephropathy. Immunofluorescence examination showing mesangial deposits of IgA1

BOX 5 Treatment of IgA nephropathy (IgAN)

Proteinuria < 1 g/day, blood pressure treatment maintain 130/80 mm Hg in patients with ACEi/ARB

Proteinuria > 1 g/day.

- Blood pressure treatment goals should be 125/75 mm Hg (not graded).
- KDIGO recommends long-term ACE-I or ARB treatment when proteinuria is > 1 g/day, with up-titration of the drug depending on blood pressure.
- KDIGO suggests ACE-I or ARB treatment, if proteinuria is between 0.5 and 1 g/day (in children, between 0.5 and 1g/day per 1.73 m^2).
- KDIGO suggests that patients with persistent proteinuria > 1 g/day, despite 3–6 months of optimized supportive care (including ACE-I or ARBs and blood pressure control), and GFR > 50 mL/min per 1.73 m^2, receive a 6-month course of corticosteriod therapy.
- KDIGO suggests the ACE-I or ARB be titrated upwards as far as tolerated to achieve proteinuria < 1 g/day.
- KDIGO suggests using fish oil in the treatment of IgAN with persistent proteinuria > 1 g/day, despite 3–6 months of optimized supportive care (including ACE-I or ARBs and blood pressure control).

Nephrotic syndrome

- KDIGO recommends treatment as for MCD in nephrotic patients showing pathological findings of MCD with mesangial IgA deposits on kidney biopsy.

RPRF/Crescentic GN

- KDIGO suggests treating with corticosteroids combined with cyclophosphamide or azathioprine in IgAN patients with crescentic IgAN with rapidly deteriorating kidney function analogous to the treatment of ANCA vasculitis.
- KDIGO suggests not using immunosuppressive therapy in patients with GFR < 30 mL/min per 1.73 m^2 unless there is crescentic IgAN with rapidly deteriorating kidney function.
- KDIGO suggests not using MMF in IgAN.
- Antiplatelet therapy and tonsillectomy are not recommended.

Repeat kidney biopsy in IgAN patients

- AKI associated with macroscopic hematuria if, after 5 days from the onset of kidney function worsening, there is no improvement. (Not Graded)
- Kidney biopsy performed during an episode of macroscopic hematuria shows only ATN and intratubular erythrocyte casts hence not advised.

GN (see above). The role of tonsillectomy, plasmapheresis, and combined therapy with heparin, warfarin and dipyridamole is unclear.

Serial monitoring of urine sediment, serum creatinine and protein excretion is recommended. While IgA nephropathy usually has a benign course, progression to ESRD is noted in approximately 20% at 10 years and 30% at 20 years. The presence of elevated serum creatinine, hypertension and nephrotic range proteinuria predict adverse prognosis; obesity, hypertriglyceridemia and hyperuricemia may hasten progression.

Patients with ESRD require dialysis or transplantation. Living-related transplant is not contraindicated. Recurrent IgA deposition in allograft is common (50%), but graft loss is rare. The risk of recurrence increases with living donor, certain human leukocyte antigen (HLA) alleles and high serum IgA. Recurrent IgA nephropathy is managed as disease in native kidneys.

IN A NUTSHELL

1. IgA nephropathy is a common primary glomerular disease characterized by mesangial IgA1 deposits.
2. Patients present with recurrent, synpharyngitic gross hematuria or asymptomatic hematuria and proteinuria. Nephrotic syndrome and crescentic GN are uncommon.
3. Management of hypertension and proteinuria, usually with ACE inhibitors, retards progression of the illness. Corticosteroids are indicated if nephrotic syndrome is present or proteinuria persists despite therapy with ACE inhibitors.

Chapter 41.7
Systemic Vasculitis and Lupus Nephritis
Ashima Gulati, Arvind Bagga

Systemic vasculitides comprise heterogeneous disorders with multiorgan involvement and variable clinical presentation. These conditions may involve small (capillaries and venules), medium arteries (renal, hepatic, mesenteric and coronary) or larger vessels (aorta and large branches) and are classified by the smallest vessel affected in a particular condition. Kidney is among the target organs frequently affected in vasculitis and its involvement is a principal cause of morbidity. Based on the clinical, laboratory and pathological features, distinction between various vasculitic disorders and characterization of disease course is usually possible. Prompt recognition by general pediatricians and early subspecialty referrals are necessary.

EPIDEMIOLOGY AND ETIOPATHOGENESIS

The annual incidence of primary vasculitis in children is approximately 20 per 100,000 population. Ethnicity has an influence on the prevalence, disease manifestations and outcome. Asian children have a higher incidence of lupus and a propensity toward a more severe disease than those of European descent. Kawasaki disease and Takayasu arteritis are more common among Asians. Genetic, environmental and immunological factors act in combination to influence disease susceptibility and pathogenesis *via* generation of autoantibodies, immune complexes, inflammatory T-cells and cytokines that initiate inflammatory damage to various organs. Antecedent infections, especially streptococcal, are implicated in many vasculitides including Henoch-Schönlein purpura (HSP), granulomatosis with polyangiitis and polyarteritis nodosa.

PATHOLOGY

Takayasu arteritis is a large vessel vasculitis characterized by focal granulomatous inflammation with multinucleated giant cells, which progress to fibrosis and vascular narrowing. Polyarteritis nodosa and Kawasaki disease have a predilection for renal and coronary arteries, respectively with focal necrotizing vasculitis and inflammatory aneurysms. The presence of arteritis and glomerulonephritis (GN) indicates small vessel vasculitis. Leukocytoclastic vasculitis in HSP and hypersensitivity vasculitis is characterized by neutrophilic inflammation, scattered nuclear debris (leukocytoclasia) and necrosis of small sized vessels. Renal histology shows focal segmental proliferative GN with or without crescent formation.

CLINICAL FEATURES

The presentation of systemic vasculitides is varied and depends on the size, site and extent of vascular involvement. Recognition of these conditions can be challenging as symptoms may be nonspecific with fever, malaise, diffuse pains; however, with evolving vascular damage more obvious and specific features develop, such as purpuric rash and evidence of organ involvement like GN. Detailed history and examination are critical, with emphasis on recent illnesses, drug exposures, family history, evidence of skin rash, four-limb blood pressure, palpation of peripheral pulses and auscultation for bruit over carotid, axillary,

aortic and renal vessels. Neurological examination is useful to rule out peripheral neuropathy and retinal vascular abnormality.

DIAGNOSIS

Blood investigations should include complete blood counts and acute phase reactants (C-reactive protein and erythrocyte sedimentation rate) to detect systemic inflammation. Other useful tests include kidney and liver function tests, urinalysis (to detect glomerular involvement), antinuclear and antineutrophil cytoplasmic antibodies (ANA, ANCA) and complement factors C3 and C4. Imaging (CT or MR angiography, conventional angiography) detects vessel abnormalities, especially in suspected medium or large vessel disease. Patients with severe renal involvement may require kidney biopsy.

CLASSIFICATION

A classification of major childhood vasculitides, based on the size of the affected vessel, is shown in **Table 1**. **Table 2** summarizes the classification criteria for major vasculitides.

SMALL VESSEL VASCULITIS

Henoch-Schönlein Purpura

Henoch-Schönlein purpura or anaphylactoid purpura accounts for about half of all systemic vasculitides. It is a leukocytoclastic vasculitis affecting children between 3-year-old and 10-year-old. Predilection for winter and spring and antecedent upper respiratory infections suggests an infectious trigger; pathogens implicated include Group A β-hemolytic *Streptococcus*, *S. aureus*, viruses (influenza, parainfluenza, Epstein-Barr, adenovirus, parvovirus) and mycoplasma. IgA-dominant immune deposits are found in small vessels.

Clinical features Henoch-Schönlein purpura is characterized by nonthrombocytopenic purpura, arthritis or arthralgia, abdominal pain and renal involvement. Purpuric rash appears on the

Table 1 Classification of childhood vasculitis

Predominantly large vessel vasculitis
• Takayasu arteritis
Predominantly medium-sized vessel vasculitis
• Childhood polyarteritis nodosa • Cutaneous polyarteritis • Kawasaki disease
Predominantly small vessel vasculitis

• *Granulomatous*
  – Wegener's granulomatosis
  – Churg-Strauss syndrome
• *Nongranulomatous*

extensor surface of legs and gluteal region but may be seen on the arms and face. The rash may be maculopapular or urticarial but soon becomes purpuric and gradually disappears over 2 weeks. Arthralgia or arthritis affects large joints, is usually oligoarticular and self-limited. Gastrointestinal manifestations may include abdominal pain, bleeding and intussusception. Renal involvement occurs in about one-third of patients within the first 4–6 weeks and almost always within 6 months. Isolated microscopic hematuria with or without proteinuria is the most common; however, children may present with nephritic or nephrotic syndrome, or rarely renal failure. Risk factors for renal involvement are an older age of onset, rash lasting for more than 1 month and severe abdominal symptoms. Atypical presentations include pulmonary hemorrhage, seizures, stroke and mental status changes.

Diagnosis Classification criteria are outlined in **Table 2**. In cases of purpura with atypical distribution, demonstration of leukocytoclastic vasculitis with IgA is required at biopsy performed at the edge of a fresh cutaneous lesion. Kidney biopsy is indicated in presence of significant proteinuria, nephrotic or nephritic syndrome and renal insufficiency.

Table 2 EULAR classification criteria for major childhood vasculitides

Henoch-Schönlein purpura	*Mandatory criterion*: Purpura or petechiae (not related to thrombocytopenia) with lower limb predominance and at least *one* of the following: *(i) Acute abdominal pain:* May include intussusception/gastrointestinal bleeding; *(ii) Histopathology:* Leukocytoclastic vasculitis or proliferative glomerulonephritis with predominant IgA deposits; *(iii) Arthritis or arthralgia of acute onset*; *(iv) Renal involvement**
Polyarteritis nodosa	*Mandatory criterion*: *Angiographic abnormalities,* e.g., aneurysm, stenosis or occlusion, and *histopathology* showing necrotizing vasculitis of medium or small-sized artery, plus one of the following: *(i) Skin involvement*: Livedo reticularis, nodules, ischemic changes; *(ii) Myalgia/muscle tenderness*; *(iii) Hypertension*; *(iv) Peripheral neuropathy*; *(v) Renal involvement**
Wegener's granulomatosis	Presence of at least three of the following: *(i) Histopathology:* Granulomatous inflammation within vessel wall or in perivascular or extravascular area; *(ii) Upper airway involvement:* Chronic purulent or bloody nasal discharge or nasal septal perforation or chronic sinusitis; *(iii) Laryngotracheal bronchial stenosis*; *(iv) Pulmonary involvement:* Chest X-ray or CT findings of nodules, cavities or infiltrates; *(v) ANCA positivity* by immunofluorescence or ELISA; *(vi) Renal involvement**
Takayasu arteritis	*Mandatory criterion*: *Angiographic abnormalities*: aneurysm/dilatation of the aorta or its main branches and one of the following: *(i) Pulse deficit or claudication or four limbs blood pressure discrepancy* (> 10 mm Hg systolic blood pressure difference in any limb); *(ii) Bruit* over large arteries; *(iii) Hypertension*; *(iv) Acute phase reactant*: High erythrocyte sedimentation rate or C-reactive protein

Ozen S, Pistorio A, Lusan SM, *et al*. EULAR/PRINTO/PRES criteria for Henoch–Schönlein purpura, childhood polyarteritis nodosa, childhood Wegener granulomatosis and childhood Takayasu arteritis: Ankara 2008. Part II: Final classification criteria. Ann Rheum Dis. 2010;69:798-806.
*Proteinuria (> 0.3 g/24 hours or > 30 mmol/mg of urine albumin/creatinine ratio on spot morning sample or ≥ 2 + on dipstick) or hematuria (> 5 red blood cells/high power field or red blood cells casts in urinary sediment) or impaired renal function (estimated GFR < 50% normal).
Abbreviations: ANCA, antineutrophil cytoplasmic antibody; ELISA, enzyme-linked immunosorbent assay; GFR, glomerular filtration rate.

Treatment Management comprises symptomatic treatment with rest and analgesia for joint pains. Administration of corticosteroids does not prevent HSP nephritis. Indications for systemic steroids include severe gastrointestinal manifestations, orchitis and severe renal involvement. Prednisolone is administered at a dose of 1–2 mg/kg/day for a week, followed by gradual reduction of the dose over 2–3 weeks. Renal disease is mild in the majority and does not require specific therapy. It is recommended that children with HSP nephritis and persistent proteinuria be treated with angiotensin converting enzyme inhibitors (ACE-I) or angiotensin receptor blockers (ARB). Children with persistent proteinuria after a trial of ACE-I or ARBs may be offered a 6-month course of corticosteroid therapy. Children presenting with severe nephritis or nephrotic syndrome are treated with corticosteroids and cytotoxic drugs. Treatment of crescentic GN consists of IV corticosteroids, cyclophosphamide and, in nonresponsive cases, plasma exchange.

Outcome Renal involvement, though self-limited, may be severe, particularly when glomerular crescents are present and can lead to end stage kidney disease in less than 1%. Persistent heavy proteinuria, hypertension and azotemia and with crescents on biopsy indicate a poor prognosis. Approximately 15–40% of patients have at least one recurrence that most commonly consists of rash and abdominal pain, each episode usually being similar but briefer and milder than the preceding one.

Antineutrophil Cytoplasmic Antibody-associated Vasculitides

The ANCA-associated vasculitides includes three classic vasculitides: microscopic polyangiitis, granulomatosis with polyangiitis (formerly Wegener's granulomatosis) and Churg-Strauss syndrome.

Microscopic Polyangiitis

Microscopic polyangiitis is a necrotizing vasculitis of small vessels with few or no immune deposits. It differs from classic polyarteritis nodosa by the presence of extensive glomerular involvement. It usually presents with renal impairment associated with proteinuria, hematuria and hypertension. Malaise, fever, anorexia and weight loss are common; occasionally rashes, arthralgia, myalgia and pulmonary hemorrhage may occur.

Antibodies directed against neutrophil cytoplasmic antigens (ANCA) might be found in patients with microscopic polyarteritis. These antibodies are also associated with Wegener's granulomatosis and other vasculitis limited to kidney. An indirect immunofluorescence assay differentiates two patterns of staining. Diffuse granular staining throughout the neutrophil cytoplasm, termed cytoplasmic (cANCA), corresponds to specificity for proteinase 3 (PR3), and is strongly associated with Wegener's granulomatosis. Concentration of fluorescence around the nucleus, known as perinuclear (pANCA), is usually associated with antibodies against myeloperoxidase (MPO). For diagnostic accuracy, testing for ANCA should also include ELISA for antigen specificity (PR3 or MPO). Approximately 80–85% patients with microscopic polyangiitis have either pANCA or cANCA, the majority having the former.

Renal biopsy shows focal, segmental necrotizing GN with fibrinoid necrosis, thrombosis of glomerular tuft segments surrounded by neutrophils. There may be extensive crescent formation and glomerular immune deposits are scarce or absent, hence the term pauci-immune crescentic GN.

Wegener's Granulomatosis

Wegener's granulomatosis or granulomatosis with polyangiitis causes granulomatous inflammation of the respiratory tract, with necrotizing vasculitis affecting small to medium-sized vessels and necrotizing GN **(Table 2)**.

Treatment of ANCA-associated Vasculitis

The management of ANCA-associated vasculitis consists of immunosuppression in two phases, induction and maintenance. Standard induction therapy includes corticosteroids and cyclophosphamide. Recent studies have examined the role of biologic medications and plasmapheresis as adjunct therapy. Maintenance therapy is using mycophenolate mofetil or azathioprine for 18–24 months. Rituximab (375 mg/m^2/week for 4 weeks), and intravenous immunoglobulin (IVIG) (2 g/kg/month) are options for refractory disease. For details on management, see chapter 41.6.

MEDIUM VESSEL VASCULITIS

Polyarteritis Nodosa

Childhood polyarteritis nodosa is a necrotizing vasculitis associated with aneurysmal nodules along walls of medium-sized muscular arteries in skin, joints, peripheral nerves, gastrointestinal tract and other organs. It is the third most common childhood vasculitides after HSP and Kawasaki disease. Age of onset ranges from 9 years to 11 years and the overall disease course is associated with fewer relapses and improved survival compared to adult-onset disease. Clinical features relate to vascular insufficiency, mostly in the skin, muscles, kidneys, and gastrointestinal tract. Involvement of the heart, peripheral and central nervous systems are less common and lungs are typically spared. Presentation usually includes malaise, fever, weight loss, abdominal pain, myalgia and arthralgia. Renal involvement, reported in 50–60%, manifests as hematuria and hypertension. In addition, testicular pain, neurological features such as focal deficits, hemiplegia, visual loss, mononeuritis multiplex and ischemic heart disease may occur. Rupture of arterial aneurysms may cause massive intra-abdominal hemorrhage. Painful subcutaneous nodules along affected vessels are a characteristic feature.

Laboratory investigations show anemia, raised ESR and thrombocytosis. Hepatitis B surface antigen is detected in few patients. Vasculitis can be confirmed on biopsy of involved muscle. Renal and hepatic angiography show irregularity, stenosis or occlusion of involved vessels; arterial aneurysms affecting the renal, mesenteric or coronary arteries are suggestive, but not specific for polyarteritis nodosa.

Initial treatment comprises corticosteroids alone or cyclophosphamide followed by maintenance therapy with mycophenolate mofetil or azathioprine. Plasmapheresis is indicated for severe organ damage. More recently, biologic agents such as rituximab have been used. Addition of antiplatelet drugs is recommended for patients with ischemia. Once controlled, the disease is self-limiting; early withdrawal of therapy may lead to relapses. The prognosis is variable with mortality ranging from 10% to 20% despite aggressive therapy.

LARGE VESSEL VASCULITIS

Takayasu Arteritis (Nonspecific Aortoarteritis)

Takayasu arteritis is a granulomatous vasculitis that affects the aorta and major branches, most commonly the renal, subclavian and carotid arteries. It is a common cause of renovascular hypertension in children in India and Asia. Detection of angiographic abnormalities (conventional, CT or MR) of the aorta or its main branches is a mandatory criterion **(Table 2)**. The early phase of the disease is characterized by systemic features (fever, anorexia, weight loss, cough, joint pains and anemia) that often go unrecognized. Features of renovascular hypertension and hypertensive complications (heart failure) develop subsequently. Patients may have claudicating pain in the extremities, absent pulses and bruits.

Though conventional angiography demonstrating stenosis or occlusion of involved vessels is the gold standard for imaging, it is invasive and cannot detect thickened vessel walls, an early sign of inflammation. CT and MR angiogram show vessel wall thickening.

Treatment consists of tapering doses of corticosteroids when the disease is detected during the acute phase. Patients with severe disease benefit from cytotoxic agents. Hypertension needs to be controlled using appropriate medications. Once the inflammatory phase is passed and stenosis has developed, reconstructive vascular surgery or balloon angioplasty with or without stenting is often required.

LUPUS NEPHRITIS

Systemic lupus erythematosus (SLE) is a chronic, multisystem autoimmune disorder characterized by widespread inflammation of connective tissues affecting the skin, joints, kidneys, heart, lungs and nervous system. Although commonly diagnosed in women during the second to fourth decades of life, disease onset is in childhood in 15–20%. Biopsy proven lupus nephritis, seen in 60–80% cases of childhood-onset SLE, is among the most common secondary glomerular diseases in childhood and is an important determinant of prognosis.

Clinical Features

Clinical presentation in children may be nonspecific. There is a higher frequency of malar rash, mucocutaneous involvement, renal involvement, seizures, fever, hemolytic anemia, thrombocytopenia and lymphadenopathy; Raynaud phenomenon, pleuritis and sicca symptoms are less common. Renal manifestations are present in almost one-half with presentations ranging from minor urinary abnormalities to severe renal insufficiency. Proteinuria, microscopic or macroscopic hematuria is common. Deranged renal function at onset is seen in 50% children with about 2% requiring renal replacement therapy. A small proportion present with a rapidly progressive GN with biopsy-proven crescentic GN. Hypertension is seen in 40% cases. Patients are at risk of arterial and venous thrombosis.

Evaluation

Investigations that help in disease evaluation and determining its severity include complete blood counts, erythrocyte sedimentation rate, C-reactive protein, renal and liver function tests and electrolytes; urine microscopy, spot protein to creatinine ratio or a 24 hours protein and creatinine excretion. Serological tests include complement C3, C4, antinuclear antibody (positive in 95% by ELISA; usually a homogenous diffuse pattern on immunofluorescence and a peripheral pattern with active disease), antidouble stranded DNA (specific for SLE; presence of high titers is related with active lupus nephritis), anti-Smith (specific to SLE and proposed to be a marker of central nervous system disease), antiphospholipid antibodies (anticardiolipin antibodies, IgG and IgM, and lupus anticoagulant; should be examined in recurrent thrombosis, livedo reticularis, chorea, cerebrovascular accidents and hypertension), anti-Ro, anti-La and antiribonucleoprotein.

Renal Histology

Kidney biopsy is required for determining prognosis and defining treatment. The WHO classification of lupus nephritis is widely accepted. A revised classification proposed by the International Society of Nephrology and Renal Pathologic Society emphasizes the utility of activity and chronicity indices while reporting biopsy specimens and standardizes definitions to encourage uniform and reproducible reporting **(Table 3)**.

Table 3 Histological classification of lupus nephritis proposed by the International Society of Nephrology Renal Pathology Society

Class	Nomenclature	Description
I	Minimal mesangial lupus nephritis	Normal appearing glomeruli by light microscopy (LM) with immune deposits confined to the mesangium by immunofluorescence (IF) or by IF and electron microscopy (EM)
II	Mesangial proliferative lupus nephritis	Mesangial proliferation by LM and mesangial deposits by IF; isolated small immune deposits by IF or EM involving the peripheral capillary walls may be present. Any subendothelial deposits by LM qualify as class III or IV
III	Focal lupus nephritis[*] (< 50% of glomeruli): active (A), active and chronic (A/C) or chronic (C) lesions	Focal lupus nephritis involving < 50% glomeruli; glomeruli display segmental endocapillary proliferative lesions, with or without capillary wall necrosis and crescent, with subendothelial deposits
IV	Diffuse lupus nephritis[**] (≥ 50% of glomeruli): Segmental (S) or global (G) lesions; (A)/(A/C)/(C)	Involvement of 50% or more glomeruli in the biopsy; lesions may be segmental or global
V[£]	Membranous lupus nephritis	Membranous lesion with global or segmental continuous granular subepithelial immune deposits with any degree of mesangial hypercellularity. Any subendothelial deposits by LM warrant a combined diagnosis of class III and V or class IV and V; however, scattered subendothelial immune deposits may be identified by IF or EM
VI	Advanced sclerosing lupus nephritis	Includes biopsies with > 90% global glomerulosclerosis with clinical or pathologic evidence of sclerosis being attributable to lupus nephritis

[*]Indicate the proportion of glomeruli with active and with sclerotic lesions.
[**]Indicate the proportion of glomeruli with fibrinoid necrosis and with cellular crescents.
[£]Diagnosis of combined class III/IV and V requires membranous involvement of at least 50% of the glomerular capillary surface area of at least 50% of glomeruli by light microscopy or immunofluorescence.

Treatment

The treatment of SLE depends on severity of the disease. No specific therapy is necessary for milder forms of lupus nephritis (class I). Such patients require management of the extrarenal manifestations and should be under regular surveillance for exacerbation of the disease. In moderate to severe active nephritis (class III and IV), treatment with high-dose oral steroids and cytotoxic drugs is indicated. Prednisolone is initially given at a dose of 1–2 mg/kg daily for 4–6 weeks and then gradually tapered to a maintenance dose of 0.2–0.3 mg/kg daily, for 2–3 years or more. Patients with class III and IV lupus nephritis are also given cyclophosphamide, preferably IV every 3–4 weeks for 6–7 pulses, or orally (2 mg/kg daily for 3–4 months). Subsequently, cyclophosphamide is replaced either by azathioprine (1–2 mg/kg per day) or mycophenolate mofetil. Patients with class V nephritis may be treated with a combination of oral prednisolone and either a calcineurin inhibitor (*e.g.,* cyclosporine) or mycophenolate mofetil. In patients with rapidly progressive renal failure or those showing sudden deterioration of renal function, 3–6 doses of IV pulse methylprednisolone (500–750 mg/m^2) may be used before administering oral corticosteroids.

Rituximab, a chimeric monoclonal antibody directed against the CD20 cell-surface receptor expressed on immature, mature and activated B-cells, is increasingly used in multiple autoimmune disorders. Rituximab may have a beneficial role in patients with severe active lupus nephritis. It is presently used to treat SLE resistant to standard mediations. Plasma exchange and IV immunoglobulin be useful in similar situations.

Prognosis

Childhood-onset lupus nephritis carries a worse renal prognosis compared with adults. Relapses of lupus nephritis occur in approximately one-third of treated patients and are associated with worsened kidney outcomes, such as doubling of serum creatinine and a higher risk for end-stage renal disease. However, mortality from renal failure is lower with increasing use of effective therapies. Kidney transplantation in patients with lupus nephritis has similar long-term patient and graft survival when matched to controls, with less than 10% risk of disease recurrence and a nonsignificant trend toward higher infection-associated mortality.

IN A NUTSHELL

1. The size, site, and extent of vessel involvement determine presentation and severity of childhood vasculitides. Newer validated classification criteria enable identification of disease course and expected severity.
2. Early diagnosis and prompt treatment may improve outcomes. Management involves a multidisciplinary team approach and long-term follow-up.
3. Manifestations of lupus nephritis are severe in children; adequate immunosuppression is necessary, but needs to be balanced with side effects of these medications.

Chapter 41.8
Alport Syndrome and Related Disorders
Mukta Mantan

Alport syndrome and thin basement membrane nephropathy (TBMN) are genetic diseases of the glomerular basement membrane involving the $\alpha3/\alpha4/\alpha5$ network of type IV collagen. Alport syndrome is an inherited progressive disease that presents typically with hematuria in childhood with progressive proteinuria and renal impairment in later years. Males with mutations in the X-linked *COL4A5* gene show progressive renal and sometimes extrarenal disease. Females who are heterozygous for a *COL4A5* mutation are carriers for the condition. TBMN is an autosomal dominant disorder characterized by microscopic glomerular hematuria, minimal or no proteinuria and normal renal function. It is often diagnosed incidentally and has an excellent prognosis.

ALPORT SYNDROME

The prevalence of Alport syndrome varies from 1 in 5,000–50,000 individuals and accounts for 1–2% population with end stage renal disease in the developed world; data from developing countries is limited.

Pathogenesis

The basement membrane of the glomerulus is formed by interweaving of type IV collagen with laminins, nidogen and sulfated proteoglycans. The type IV collagen family of proteins comprises six isomeric chains, designated as $\alpha1$ (IV) to $\alpha6$ (IV). These chains show extensive sequence homology and share basic structural features. Each type IV collagen molecule is a heterotrimer composed of three α chains. The genes *COL4A1* to *COL4A6* encoding the six-chains of collagen IV-$\alpha1$ (IV) through $\alpha6$ (IV) are expressed in different membranes at various steps of embryonic development. The embryonic kidney contains $\alpha1\alpha1\alpha2$ collagen IV protomers while in normal, mature kidney collagen $\alpha3\alpha4\alpha5$ (IV) trimers are found in glomerular basement membrane, Bowman capsule and basement membrane of distal tubules; these timers are also found on ocular and cochlear basement membranes. The $\alpha3\alpha4\alpha5$ protomer has multiple disulfide bonds rendering it resistant to proteolysis and conferring mechanical strength. Mutations in *COL4A3*, *COL4A4* or *COL4A5*, the genes encoding $\alpha3$, $\alpha4$ and $\alpha5$ chains result in incorrect formation of collagen IV protomers that are degraded allowing a persistence of the embryonic network of the basement membrane, which becomes weak with time. A compensatory overproduction of atypical laminin isoforms (laminin $\alpha1$ and $\alpha5$) and the altered type IV collagen contribute to increased permeability of the basement membrane and production of transforming growth factor (TGF$\beta1$) resulting in glomerulopathy and fibrosis.

Genetics

Of three genetic forms of Alport syndrome, the X-linked form is the most common (85% patients) and is caused by mutations in *COL4A5* gene. Males afflicted with the condition are hemizygotes carrying a single mutant gene while females are heterozygotes with one normal and other mutant gene and are mostly carriers. All affected males progress to renal failure; the course is usually benign in females. The recessive form of the disease occurs in 10–15% patients due to mutations in both alleles of *COL4A3* or *COL4A4* gene located at chromosome 2q35-37. Heterozygous mutations in these genes results in autosomal dominant form of disease that occurs in 5% subjects. Most patients with dominant disease are asymptomatic or present with isolated hematuria that is nonprogressive.

Genetic testing for Alport syndrome is limited to a few laboratories worldwide. More than 200 mutations have been identified in *COL4A3* and *COL4A4* genes. The spectrum of mutations is broad and provides insight into the heterogeneity of Alport syndrome with respect to age at renal failure and features such as deafness, leiomyomatosis and antiglomerular basement membrane (anti-GBM) nephritis. The identification of variants of the *COL4A5* gene helps in confirming the diagnosis and understanding the prognosis.

Clinical Features

Renal manifestations begin as hematuria that later progress to proteinuria and end stage renal disease. Pedigrees with the disease vary in rapidity of onset of renal failure. Patients with nonsense or missense, frame shift mutations or large deletions in their chromosomes develop end stage renal disease by 30 years of age while individuals with splice variants or exon-skipping mutations show renal failure after 30 year of age. Sensorineural hearing loss progressively develops in late childhood, in 80% afflicted boys and 25–30% girls. The hearing loss plateaus at around 80–90 decibels and some useful hearing always remains; patients improve with hearing aids. The ocular features are primarily an anterior lenticonus; the lens slowly becomes conical in shape and leads to myopia that can be corrected with appropriate lenses. Rarely lens extraction may be required. Macular flecks are white flecks scattered around the macula and also at the periphery; they do not affect vision. Ocular changes occur in 30–40% of males with X-linked disease and 15% affected females.

The association of leiomyomatosis (smooth muscle tumors) of the esophagus and the tracheobronchial tree is reported in 20–30 families, in association with deletions involving *COL4A5* and *COL4A6* genes. Symptoms appear in late childhood and include dysphagia, vomiting, epigastric pain, cough, stridor and recurrent bronchitis.

Diagnosis

Alport syndrome should be suspected in patients (especially males) with persistent glomerular microscopic hematuria once structural abnormalities of the kidney and urinary tract have been ruled out. A positive family history of hematuria or renal failure may suggest the diagnosis. Renal biopsy changes are less marked in children compared to adults. Light microscopy shows variable thickening of the glomerular basement membrane. Electron microscopy shows initial thinning of the glomerular basement membrane, that later changes to basket weaving and lamellation.

On indirect immunofluorescence an absence of $\alpha3$, $\alpha4$ and $\alpha5$ chains of type IV collagen from basement membrane of the glomeruli and the distal tubules helps in diagnosis, since the finding is exclusive to Alport syndrome. Examination of skin biopsies by immunofluorescence for the expression of $\alpha5$ (IV) collagen in the epidermal basement membrane can also identify X-linked condition. However normal expression of type IV collagen α chains does not exclude the diagnosis. Most heterozygote females with the condition would have normal skin biopsies. A firm histological diagnosis of the syndrome is not always possible despite careful study of the pedigree and histopathology.

The diagnosis of Alport syndrome is confirmed if there is a lamellated glomerular basement membrane or a pathogenic mutation in *COL4A5* gene or two pathogenic *COL4A3* or *COL4A4* mutations. Genetic testing has a sensitivity of more than 90%

for the diagnosis of X-linked disease; more than 700 variants are described.

Treatment

The presence of proteinuria, hearing loss, lenticonus, retinopathy and deficient collagen IV α5 chains in glomerular basement membrane in male patients correlate with an increased likelihood of early onset renal failure. The hearing defect improves on use of hearing aid; the myopia due to lenticonus can be corrected. Angiotensin converting enzyme inhibitors reduce proteinuria and delay the onset of renal failure in children with X-linked disease. The additional use of angiotensin receptor blockers and/or aldosterone inhibitors may further reduce proteinuria, but combined therapy should be used cautiously.

Renal replacement therapy may be required when patients reach end stage renal disease. Family renal donors should be carefully screened for Alport syndrome. The outcomes of renal transplantation are excellent. Post-transplant monitoring should include early identification of anti-GBM nephritis that occurs in about 3% of transplanted males.

THIN BASEMENT MEMBRANE NEPHROPATHY

Thin basement membrane nephropathy is an inherited disorder of glomerular basement membrane that is transmitted in an autosomal dominant manner. It affects about 1% of the population. It differs from Alport syndrome in being a more benign condition and does not have any extrarenal manifestations. Familial TBMN has been localized to *COL4A3* or *COL4A4* in some kindreds. Immunohistological studies of type IV collagen in basement membrane of TBMN do not revealed any abnormalities.

Clinical Features

Patients with TBMN usually present with intermittent or persistent microscopic hematuria during childhood. Proteinuria and hypertension are rarely reported. While the disease is non-progressive, the risk of renal failure is increased if there is coincidental renal disease or diabetes.

Histology

Light microscopy and immunofluorescence study do not reveal any specific changes. Electron microscopy shows glomerular basement membrane thinning. While the thickness of the basement membrane in childhood varies between 200 nm and 250 nm, values below 200 nm suggest thinning. The basement membrane is thinned in the majority of capillary loops, and at least 50% of the membrane is thinned in individual capillaries.

Diagnosis

Presence of a family history of hematuria in multiple generations without progression to end stage renal disease suggests the diagnosis. Ophthalmological and ocular examinations help in differentiating from Alport disease. Presence of proteinuria, hypertension, renal dysfunction or other atypical features may necessitate renal biopsy.

Treatment

Most patients have a good prognosis. Careful follow-up every 1–2 years with measurement of blood pressures and kidney function tests is recommended. Rarely patients may show hypertension or significant proteinuria, which should be treated with ACE inhibitors.

OTHER INHERITED CONDITIONS

Pierson Syndrome

Patients with this condition have ocular abnormalities (buphthalmos, microcoria, cataract and retinal abnormalities) in association with congenital nephrotic syndrome. The gene for the condition, *LAMB2* gene, encodes for laminin β2 chains.

Nail-Patella Syndrome

This autosomal dominant disorder is characterized by the presence of dystrophic nails, hypoplastic or absent patella, dysplasia of elbow and iliac horns and renal disease. The gene for the condition is located on chromosome 9q34 (*LMX1B*). Renal disease varies from microscopic hematuria and mild proteinuria to nephrotic syndrome; few patients have hypertension. The risk of progression to end stage renal disease is low (< 10%). Renal biopsy does not show specific findings on light microscopy; electron microscopy reveals moth eaten appearance of the basement membrane.

Fabry Disease

This is an X-linked disorder of glycosphingolipid metabolism, due to deficient enzyme, lysosomal hydrolase α galactosidase A, that results in involvement of kidneys, heart and peripheral and central nervous systems. Patients present in childhood with paresthesias and pain in hands and feet. Angiokeratomas of the skin develop by second decade. Renal involvement is characterized by mild to moderate proteinuria and microscopic hematuria. Nephrotic syndrome is unusual and end stage renal disease develops between third and sixth decades. The diagnosis is confirmed by demonstrating decreased enzyme activity in serum, leukocytes or cultured skin fibroblasts; slit lamp examination shows corneal opacities. The role of recombinant enzyme replacement in preventing or delaying renal failure is being examined.

IN A NUTSHELL

1. Alport syndrome is an X-linked condition where the glomerular basement membrane undergoes progressive thickening. Males with persistent microscopic hematuria should be suspected for the condition and undergo hearing assessment and eye evaluation.
2. Renal biopsy of children with Alport syndrome may be normal on light microscopy; electron microscopy reveals basket weaving of the basement membrane, while indirect immunofluorescence shows absence of α3, α4 and α5 chains of type IV collagen from GBM.
3. Early use of angiotensin converting enzyme inhibitors delays progression of renal failure.
4. Thin basement membrane nephropathy, a close differential of Alport syndrome, occurs with equal frequency in both genders. The outcomes are good and end stage renal disease is rare.

Chapter 41.9
Proteinuria
Sushmita Banerjee

In the healthy state, urine contains minimal protein. The barrier to protein excretion is at the level of glomeruli, where size of protein molecules and their negative charge inhibits glomerular filtration. The minimal protein that passes through into the glomerular filtrate is reabsorbed in the proximal tubule. There is some tubular secretion, in form of low molecular weight proteins (70% being Tamm-Horsfall protein). The normal range of urinary protein excretion in children is less than 4 mg/m^2/hour in a timed urine sample, less than 100 mg/m^2/day, or less than 0.2 (0.5 in infants) mg of protein/mg of creatinine in a spot urine sample. Larger excretion of protein is defined as proteinuria **(Table 1)**.

Any damage causing increase in the pore size or disruption of negative charge of the glomerular basement membrane results in proteinuria which may be selective where mainly albumin is excreted, or nonselective, where proteins of higher molecular weight such as transferrin and IgG are excreted. Proteinuria in such cases exceeds the proximal tubular capacity of reabsorption. Tubular proteinuria, usually of smaller magnitude, occurs when a tubular pathology results in lack of reabsorption of low molecular weight proteins (e.g., beta 2 microglobulin, retinol binding protein). Tubular injury can also lead to release of tubular proteins such as neutrophil gelatinase-associated lipocalin into the urine. Albuminuria is a marker of renal pathology. Subtle glomerular injury may be associated with urinary albumin values between 30 mg/g and 300 mg/g of creatinine (termed microalbuminuria), while greater values indicate more significant disease. These parameters are commonly used for the early detection of renal injury.

Orthostatic proteinuria occurs in the upright position but subsides after rest. This is determined by checking urinary protein excretions after overnight sleep and comparing it with a value obtained later in the day when the patient has been upright for some time. This phenomenon is usually seen in older children and thought to represent physiological changes in renal hemodynamics, and is generally benign in nature. It requires occasional monitoring but no further evaluation. *Exercise-induced proteinuria* occurs during or after exercise but reverts to normal ranges when tested several days later. *Transient proteinuria* occurs with acute diseases such as dehydration, urinary infection, acute kidney injury or febrile illness. It subsides once the acute illness resolves. Patients with persistent proteinuria, that continues for at least 4 weeks and is present in repeated measurements, need evaluation.

Table 1 Definitions: quantification of proteinuria

Terminology	Protein (mg/m^2/hour)	Protein : creatinine ratio (mg/mg)
Proteinuria	≥ 4	≥ 0.2
Nonnephrotic range proteinuria	$\geq 4 - < 40$	$\geq 0.2 - < 2$
Nephrotic range proteinuria	≥ 40	≥ 2

DETECTION OF PROTEINURIA

Proteinuria is detected semiquantitatively using dipstick on an early morning specimen. Heat precipitation or sulfosalicylic acid tests are also useful. For quantitative estimation, the first or second urine specimen, used for ratio of urinary protein to creatinine, has satisfactory correlation with 12- or 24 hours specimens. While cumbersome to obtain, the 24 hours sample is considered standard as it accounts for differences in proteinuria with time and fluid intake.

EPIDEMIOLOGY

Proteinuria may be associated with different physiological and pathological events. A Panel on proteinuria, albuminuria, risk, assessment, detection, and elimination reported that after four tests, 10.7% of children have proteinuria in one of four specimens. However, only 0.1% had positive protein in all specimens.

APPROACH TO A PATIENT WITH PROTEINURIA

Patients with proteinuria require detailed clinical history and evaluation. This is followed by laboratory tests and imaging as indicated. Patients with fever, abdominal lump, oliguria, hematuria, edema, hypertension and fluid overload have significant pathology and require further evaluation **(Table 2)**. Those with *nephrotic syndrome* have nephrotic range proteinuria, hypoalbuminemia, edema and hyperlipidemia. Patients with *glomerulonephritis* show raised urea and creatinine, hypertension and *active urinary sediment* with red cells and casts, and lower degree of proteinuria. Patients with renal or bladder tumors, obstructive uropathy and renal stones may present with pain or abdominal lump. Investigations include urine microscopy and culture, and blood tests for urea, creatinine, electrolytes, albumin and cholesterol. Serological tests such as ASOT, ANA, antidsDNA and ANCA may also be required. Renal imaging is necessary to diagnose structural abnormalities and to differentiate between acute and chronic kidney disease. A renal biopsy is done where the diagnosis is not clear or if histopathological details are required for management.

Asymptomatic proteinuria is detected incidentally. If it persists on repeated examinations including on an early morning sample (to exclude orthostatic and exercise-induced proteinuria), it should be confirmed on a timed urine sample. Family history is taken for conditions like Alport syndrome and polycystic kidney disease. Renal functions are assessed and urinalysis is done for hematuria. Eye examinations and audiometry is required to exclude inherited diseases. Renal ultrasonography and further imaging is done to evaluate for specific conditions.

The presence of significant hematuria or renal dysfunction makes significant pathology likely, and detailed evaluation should follow (as mentioned above). Patients with isolated asymptomatic proteinuria need to be evaluated and monitored over the long-term. A kidney biopsy is necessary in patients showing increasing proteinuria.

MANAGEMENT

Nonspecific reduction of proteinuria has a renoprotective role. Drugs that inhibit the renin-angiotensin system, i.e., angiotensin converting enzyme inhibitors and angiotensin receptor blocker have significant antiproteinuric action. They act by causing vasodilation of the efferent glomerular arteriole and thereby reducing GFR and subsequently protein excretion. These

Table 2 Differential diagnosis of symptomatic proteinuria

Presentation	Clinical features	Differential diagnosis	Investigations
Nephrotic syndrome	Oliguria Edema	Nephrotic syndrome (varied histology)	Creatinine, albumin Cholesterol Renal biopsy

Abbreviations: C3, complement 3; GN, glomerulonephritis; HIV, human immunodeficiency virus; LDH, lactate dehydrogenase.

medications should be used under supervision, since they might be associated with reduced GFR and risk of hyperkalemia, especially in volume depleted states.

IN A NUTSHELL

1. Proteinuria is a nonspecific indicator of renal injury.
2. Patients with symptomatic and persistent proteinuria require detailed evaluation.
3. Blockade of the renin angiotensin axis is beneficial in reducing severity of proteinuria and improving outcomes.

Chapter 41.10
Nephrotic Syndrome

Arvind Bagga, Aditi Sinha

Nephrotic syndrome, characterized by heavy proteinuria (> 1 g/m², 40 mg/m²/hour or spot urine protein/creatinine > 2), hypoalbuminemia (serum albumin < 2.5 g/dL), hyperlipidemia (serum cholesterol > 200 mg/dL) and edema, is a common chronic kidney disease in children, with an incidence of about 16 per 100,000 children. The disease is idiopathic or primary in more than 90% cases; a secondary cause, *e.g.,* systemic lupus, hepatitis B or C, amyloidosis or Henoch-Schönlein purpura, is uncommon. Response to corticosteroid therapy is the most important determinant of outcome. **Box 1** lists important definitions of disease course. The majority of patients are steroid responsive, with variable disease course but satisfactory outcomes.

PATHOLOGY

In over 80% patients, the histology shows insignificant glomerular abnormalities on light microscopy, termed minimal change disease **(Fig. 1A)**. While immunofluorescence is negative for deposits of immunoglobulins or complement, electron microscopy reveals effacement of podocytes foot processes with disruption and disorganization of actin filaments. A small proportion shows mesangial proliferation (presence of 3–4 cells per mesangial lobule). A small proportion of patients with steroid sensitive nephrotic syndrome have focal segmental glomerulosclerosis (FSGS), with sclerosis involving a segment of the glomerular tuft **(Fig. 1B)**. Collapsing glomerulopathy, a subtype of FSGS, associated with human immunodeficiency virus or parvovirus infection, shows rapid progression to end stage renal disease.

Histology in patients with steroid-resistant nephrotic syndrome shows minimal change disease and FSGS in 30–40% patients each, and mesangioproliferative glomerulonephritis in a small group. About 10–15% patients with steroid resistance show membranoproliferative glomerulonephritis (MPGN), membranous nephropathy, IgA nephropathy or amyloidosis. Some syndromic forms of nephrotic syndrome are associated with diffuse mesangial sclerosis.

PATHOGENESIS

The pathogenesis of minimal change disease remains unclear. Proteinuria results from altered permeability of the glomerular filtration barrier, which comprises the podocyte slit diaphragms, glomerular basement membrane and fenestrated capillary endothelium. Disease relapses often follow minor infections or immunization, and it is proposed that altered cell-mediated immunity possibly associated with T helper 2 immune response causes T-cells to release an uncharacterized circulating factor that increases glomerular permeability. The hypothesis is supported by the disease association with Hodgkin lymphoma, asthma and atopy, response to therapy with agents inhibiting T-cell function, occurrence of remission following measles and lack of inflammation on histology. Proposed circulating factors include interleukin 13, angiopoietin-like-4 and CD80 for minimal change and soluble urokinase plasminogen activator receptor, vascular endothelial growth factor and circulating proteases like hemopexin in FSGS.

Other workers speculate that disease relapses occur when microbial products activate innate immune responses to trigger toll like receptors on podocytes. Proteinuria in experimental models is linked to increased podocyte expression of CD80 (B7-1), a dendrite-associated receptor that mediates co-stimulatory signaling in T-cells. It is proposed that an imbalance of T helper 17 and T regulatory responses perpetuates persistent CD80 activation on podocytes, leading to proteinuria. Further, the ability of rituximab, an anti-B-cell agent, to sustain remission in steroid sensitive disease suggests that B-cell-mediated immune responses are important, including crosstalk between B-cells and T helper

---

BOX 1 Definitions

Nephrotic range proteinuria: 3 + /4+ (300–1,000 mg/dL) urine protein by dipstick on first morning urine for 3 consecutive days, spot protein/creatinine ratio > 2 mg/mg or urine protein excretion > 40 mg/m²/hour

Remission: Urine protein < 4 mg/m²/hour or nil/trace for three consecutive early morning specimens

Relapse: Urine protein more than 40 mg/m²/hour or 3+ or 4+ for three consecutive early morning specimens, having been in remission previously

Frequent relapses: Two or more relapses within 6 months or four or more relapses in 12 months

Steroid dependence: Two consecutive relapses during corticosteroid therapy or within 14 days of its discontinuation

Steroid resistance: Absence of remission despite therapy with prednisolone at a dose of 2 mg/kg/day for 4 weeks

cells. Another aspect that might have a role in disease pathogenesis is the regulation of actin dynamics, with emphasis on signaling pathways between slit diaphragm and actin cytoskeleton that regulate podocyte morphology and motility.

About 10–25% of patients with sporadic steroid-resistant nephrotic syndrome show mutations in genes encoding key proteins in the slit diaphragm, podocyte cytoskeleton, glomerular basement membrane or mitochondria, or encode transcription factors necessary for normal development. **Table 1** lists genes known to be altered in patients with steroid resistance, particularly familial forms. It is expected that the use of Nextgen sequencing techniques shall lead to further understanding of disease biology in steroid-resistant nephrotic syndrome.

STEROID SENSITIVE NEPHROTIC SYNDROME

Presentation and Initial Evaluation

Patients usually present between 2 years and 5 years of age with insidious onset of edema, first periorbital and subsequently on legs and abdomen. The presence of sustained hypertension, impaired renal function and persistent microscopic hematuria suggest the possibility of significant glomerular lesions. History and physical examination should focus on secondary etiology, prior therapies and evidence of infections.

Suggested evaluations at onset of nephrotic syndrome include: (1) urinalysis for proteinuria, red cells and casts; (2) blood levels of urea, creatinine, albumin, cholesterol; (3) complete blood counts; and (4) tuberculin test. Precise quantitative assessment of proteinuria is not necessary for diagnosis. Depending on clinical and laboratory findings, the following may be required: (1) C3 and antistreptolysin O (if gross or persistent microscopic hematuria); (2) chest X-ray (positive tuberculin test; history of contact with tuberculosis); (3) hepatitis B surface antigen (recent jaundice, elevated transaminases); (4) antinuclear antibodies (suspected systemic lupus); and (5) urine culture (features of urinary tract infection).

Renal Biopsy

A renal biopsy is not required to confirm the diagnosis of minimal change disease before starting treatment. A biopsy is recommended in children with atypical features at onset, including: (1) age less than 1 year or more than 16 years; (2) gross or persistent microscopic hematuria; (3) low blood C3; (4) sustained severe hypertension; (5) impaired renal function not attributed to hypovolemia; and (6) suspected secondary cause. Patients in whom a diagnosis of initial or late steroid resistance is made require renal biopsy to determine the underlying pathology. A renal biopsy is done prior to therapy with calcineurin inhibitors. The specimen is examined by light, immunofluorescence and electron microscopy.

Management of the Initial Episode

The child should receive a high protein diet. Salt is restricted to the amount in usual cooking and salty snacks avoided. Associated infections require treatment. Diuretics are administered only if edema is significant, using them cautiously to avoid overzealous weight loss. Furosemide (1–4 mg/kg/day in two divided doses) alone or with an aldosterone antagonist, spironolactone (2–3 mg/kg/day in two divided doses) is adequate.

Therapy with corticosteroids results in remission of proteinuria, usually by 10–14 days, diuresis and loss of edema. The initial (first) episode of nephrotic syndrome should be treated adequately, both in terms of dose and duration of corticosteroids. Only prednisolone and prednisone are of proven benefit in the treatment of proteinuria. Other agents such as deflazacort, methylprednisolone, dexamethasone, betamethasone, triamcinolone or hydrocortisone should not be used. Prednisolone is administered after meals to reduce gastrointestinal side effects; antacids are not required unless there is gastrointestinal intolerance. Prednisolone is given at a dose of 60 mg/m^2 in single or divided doses for 6 weeks, followed by 40 mg/m^2 as a single morning dose on alternate days for the next 6 weeks. Therapy with corticosteroids is then stopped. Prolongation of initial steroid therapy to 12 weeks is associated

Table 1 Inherited defects in patients with steroid resistant nephrotic syndrome

Gene	Protein	Location	Histology	Phenotype
NPHS1	Nephrin	Slit diaphragm	Microcystic dilatation of tubules; progressive mesangial sclerosis	Congenital nephrotic syndrome

Abbreviations: DMS, diffuse mesangial sclerosis; FSGS, focal segmental glomerulosclerosis; SRNS, steroid-resistant nephrotic syndrome; ^AD, autosomal dominant.

with significantly reduced risk for subsequent relapses compared to briefer courses. While a few studies support that tapering the dose of corticosteroids over an additional 8–12 weeks is useful, such prolongation was not shown to be beneficial in recent studies, and requires consideration of the risk of adverse effects.

Parent Education
Parents should be explained about the disease and the usual outcome. They are taught how to examine urine for protein, which is done periodically to detect a relapse. No dietary restrictions are imposed during periods of remission.

Subsequent Course
Around 15–25% patients have only a single episode of the illness, while the majority shows relapses. Infrequent and frequent relapses are noted in 25–40% patients each; 15–20% remains in remission while on therapy and relapse whenever the dose is reduced or within 2 weeks of its discontinuation (steroid dependence). Almost 10% patients either do not respond to initial treatment with prednisolone, or do so transiently and later cease to respond (steroid resistant).

Management of Relapse
Relapses are often triggered by minor infections; therapy of infectious illness might result in remission of 1+/2+ proteinuria. However, persistence of 3+/4+ proteinuria requires treatment for relapse. Prednisolone is given at a dose of 2 mg/kg/day until protein is negative/trace for 3 consecutive days, and then on alternate days at a dose of 1.5 mg/kg for 4 weeks. Treatment for a relapse usually lasts for 5–6 weeks, and there is no evidence that prolonged therapy of a relapse determines the outcome of the illness. If the patient is not in remission despite 2 weeks treatment with daily prednisolone, the treatment is extended for 2 more weeks. Patients showing no remission despite 4 weeks' treatment are labeled as *late steroid resistance*.

The first 2–3 relapses are treated in the manner described above. Once the pattern of relapses is known, therapy is individualized. Patients with infrequent relapses continue to receive treatment for individual relapses as outlined above.

Infrequent Relapses
Patients suffering from three or fewer relapses a year should receive 5–6 weeks treatment for each disease relapse as described above.

Frequent Relapses and Steroid Dependence
Patients with frequent relapses or steroid dependence require prolonged treatment in order to maintain disease remission. Strategies used to maintain remission are described in **Table 2**.

Long-term, Alternate Day Steroids
This is the usually the first strategy in managing patients with frequent relapses. Following treatment of a relapse, the dose of prednisolone is gradually tapered to a small dose given on alternate days to maintain the patient in remission. This strategy is effective in maintaining remission in 40–50% patients. Evidence suggests that changing the frequency of administration of prednisolone from alternate day to daily for 5–7 days during minor infectious illnesses is effective in preventing infection precipitated relapses.

Steroid Sparing Agents
The use of an alternative agent should be considered in patients with: (1) prednisolone threshold (for maintaining remission) higher than 0.5–0.7 mg/kg on alternate days, or (2) features of corticosteroid toxicity. The agents used are listed below:

Levamisole This agent is effective in reducing relapses and steroid requirement in many patients with frequent relapses and steroid dependence. The dose of prednisolone is decreased every 2–4 weeks to 0.25–0.5 mg/kg on alternate days. While therapy with prednisolone may be discontinued in some cases, many patients continue to require a small dose on alternate days. Adverse effects are uncommon. Leukocyte counts are monitored every 2–3 months.

Cyclophosphamide Therapy with cyclophosphamide is effective in ensuring sustained steroid free remission in a significant proportion of patients. The agent is preferred in patients with: (a) significant steroid toxicity, (b) severe relapses with episodes of hypovolemia, life-threatening infections or thrombosis, and (c) poor compliance or difficult follow-up. Children older than 7–8 years, those with frequent relapses and lower steroid threshold do better than those who are younger or have steroid dependence.

In view of its toxicity profile **(Table 2)**, the cumulative dose of cyclophosphamide should not exceed 168 mg/kg, and repeat courses are avoided. Leukocyte counts are monitored every 2 weeks and the medication discontinued if below 4,000/mm^3. Fluid intake is increased and the child is encouraged to void frequently. The dose of prednisolone is 1–1.5 mg/kg on alternate

Table 2 Alternative agents in steroid sensitive nephrotic syndrome

Agent	Dose	Duration	Adverse effects
Long-term alternate day prednisolone	0.3–0.7 mg/kg on alternate days	9–24 months	Cushingoid habitus, short stature, hypertension, cataract, glaucoma
Levamisole	2–2.5 mg/kg on alternate days	1–3 years	Rare: leukopenia, flu-like illness, rash, seizures
Cyclophosphamide*	2–2.5 mg/kg daily	8–12 weeks	Leukopenia, nausea, nail discoloration, alopecia Prolonged therapy: gonadal toxicity, malignancies
Mycophenolate mofetil	600–1,000 mg/m^2/day; 20–25 mg/kg/day	1–3 years	Gastrointestinal discomfort, diarrhea, leukopenia
Cyclosporine A (CyA) or tacrolimus (Tac)*	4–5 mg/kg/day; 0.1–0.2 mg/kg/day (target trough 80–120 ng/mL; 3–7 ng/mL, respectively)	2–3 years	Acute, chronic nephrotoxicity CyA > Tac: hirsuitism, gum hyperplasia, hypertension, high cholesterol Tac > CyA: high sugar and transaminases, diarrhea, headache, seizures
Rituximab*	375 mg/m^2 weekly	2–4 doses	Infusion reactions (rash, fever, chills, anaphylaxis); synovitis, agranulocytosis; acute lung injury

These agents are used in successive order from top to bottom. Agents marked with an asterisk (*) are preferred in patients with significant steroid toxicity (cataracts, severe stunting, obesity) or if disease relapses are associated with life-threatening complications (thrombosis, severe infections).

days during cyclophosphamide therapy; subsequently steroids are tapered and discontinued over 4–6 weeks. Another alkylating agent, *chlorambucil,* though effective has significant additional toxicities and a low margin of safety, and is not recommended.

Mycophenolate mofetil The use of mycophenolate mofetil in large case series of patients with relapsing nephrotic syndrome has been associated with reduced relapse rates and significant steroid sparing. Tapering doses of prednisolone are administered for 6–12 months. Therapy is generally safe and associated with few side effects. Leukocyte counts are monitored every 1–2 months and treatment withheld if below 4,000/mm³.

Cyclosporine and tacrolimus Therapy with either of these agents is indicated in patients with frequent relapses that fail to benefit with levamisole, cyclophosphamide and/or mycophenolate mofetil. Both agents have strong steroid sparing potential, with steroid discontinuation achieved in a majority of patients. However, treatment is associated with significant risk of adverse effects and cautious use under the supervision of an expert is necessary. Therapy with either agent is administered for 2–3 years while targeting trough levels **(Table 2)** and monitoring renal function every 3 months; rise of creatinine more than 25% is of concern. In view of risk of nephrotoxicity, a renal biopsy is done prior to and after 2–3 years of therapy.

Rituximab This monoclonal anti-CD20 antibody has been shown to have efficacy in patients with steroid-dependent nephrotic syndrome. Therapy is recommended in patients with marked steroid dependence not responding satisfactorily to other therapies, or having toxicity to other drugs. Rituximab should be administered under close supervision only at specialized centers.

STEROID-RESISTANT NEPHROTIC SYNDROME

The diagnosis of steroid resistance is made if there is lack of remission despite treatment with prednisolone, at a dose of 2 mg/kg/day (60 mg/m²/day) for 4 weeks **(Box 1)**. The definition is based on the knowledge that 95% patients with steroid sensitive nephrotic syndrome achieve remission within 4 weeks of steroid therapy, and that longer therapies are associated with high incidence of medication-related adverse effects. Care is taken to exclude systemic infections (*e.g.,* peritonitis, cellulitis, respiratory tract infections), which might result in persistent proteinuria. Initial resistance is defined by the lack of remission at the first episode of nephrotic syndrome, and late resistance is considered in patients who are steroid sensitive initially, but show steroid resistance during a subsequent relapse. The management of these patients is difficult, with patients showing variable response to immunosuppression, adverse effects of prolonged therapy and risk of progressive renal damage.

Evaluation

Baseline assessment of renal function, levels of albumin and cholesterol, and quantification of urinary protein loss (spot urine protein to creatinine ratio in young children; or 24 hours protein excretion) are essential to guide management and evaluation of response to therapy.

Children diagnosed with steroid-resistant nephrotic syndrome should undergo renal biopsy before instituting specific treatment. While patients with minimal change disease show a satisfactory response to therapy, presence of FSGS with tubulointerstitial changes is associated with less satisfactory outcomes. The diagnosis of entities such as MPGN and membranous nephropathy is important, since their management differs from idiopathic minimal change and FSGS. All patients should be evaluated for hepatitis B and C virus infection, particularly if renal histology shows membranous nephropathy or MPGN.

About 10–20% patients with familial and sporadic steroid resistance might carry homozygous or compound heterozygous mutations in genes encoding podocyte proteins, most commonly podocin (*NPHS2*), nephrin (*NPHS1*) and Wilms tumor (*WT1*). These patients are usually unresponsive to immunosuppressive medications, progress rapidly to end stage renal disease, and unlike nongenetic FSGS (which recurs after transplantation in 30%), do not show post-transplantation recur. Patients with syndromic forms have onset of disease in early childhood, e.g., Denys-Drash syndrome (diffuse mesangial sclerosis, Wilms tumor), Frasier syndrome (FSGS, male pseudohermaphroditism, gonadoblastoma) and Pierson syndrome (diffuse mesangial sclerosis, microcoria, neurological abnormalities). Where facilities exist, mutational analysis should be offered to patients with: (1) congenital nephrotic syndrome (onset below 3 months of age), (2) family history of steroid resistance, (3) sporadic initial steroid resistance that does not respond to therapy with cyclophosphamide or calcineurin inhibitors, and (4) girls with steroid-resistant FSGS.

Management

Patients with idiopathic steroid resistance secondary to minimal change disease, FSGS or mesangioproliferative glomerulonephritis are treated similarly. Patients with minimal change disease demonstrate higher rates of remission and better prognosis. *The chief factor predicting renal outcome is the response of proteinuria to therapy rather than the renal histology.* The aim of therapy in patients is thus to induce and maintain remission of proteinuria, while avoiding medication-related adverse effects. Most regimens use a combination of an immunosuppressive agent with prednisolone (given on alternate days) and an angiotensin converting enzyme inhibitor **(Table 3)**.

Calcineurin Inhibitors (Cyclosporine or Tacrolimus)

Treatment with calcineurin inhibitors is considered *first line* for patients with steroid resistance. Cyclosporine and tacrolimus are effective in inducing complete or partial remission in 60–80% patients. Adverse effects are common, as described above, and require close monitoring.

Cyclophosphamide

Oral cyclophosphamide administered alone or with oral steroids, has limited efficacy in inducing remission. Cyclophosphamide has also been used, with modest success, either in the intravenous form or in combination with intravenous steroids. Intravenous cyclophosphamide, when administered monthly for 6 doses along with tapering doses of prednisolone, induces remission in 40–50% patients.

Pulse Corticosteroids with Oral Cyclophosphamide

Pulses of IV methylprednisolone or dexamethasone have been used in combination with oral cyclophosphamide with moderate efficacy. The risk of steroid toxicity is high, with a significant proportion of patients developing systemic infections, hypertension and electrolyte abnormalities.

Other Agents

Rituximab has been reported to be successful in inducing disease remission in 25–30% patients. Its safety and efficacy needs to be established in larger series. Other therapies that have shown promise, in anecdotal reports, include the combination of cyclosporine and mycophenolate mofetil, abatacept and plasmapheresis.

Adjunctive Therapies

Prednisolone Prednisolone is a component of all regimens. It is administered on alternate days at 1 mg/kg day for 1–3 months,

Table 3 Agents for management of steroid resistant nephrotic syndrome

Agent	Dose	Duration	Efficacy	Adverse effects
Calcineurin inhibitors				
Cyclosporine (CsA)	4–5 mg/kg/day	12–36 months	50–80%	Common: Acute and chronic nephrotoxicity; hirsuitism and gum hyperplasia (CsA > Tac); hypertension; high cholesterol (CsA > Tac); hyperglycemia (Tac); elevated transaminases; neurotoxicity with headache and seizures (Tac > CsA)
Tacrolimus (Tac)	0.1–0.2 mg/kg/day	12–36 months	70–85%	
Cyclophosphamide				
Intravenous	500–750 mg/m^2	6 pulses	40–50%	Leukopenia; alopecia; nausea and vomiting (IV > oral); gonadal toxicity; hemorrhagic cystitis (IV > oral)
Oral	2–2.5 mg/kg/day	12 weeks	20–25%	
High dose corticosteroids with cyclophosphamide				
Methylprednisolone or	20–30 mg/kg IV		30–50%	Hypertension, hypokalemia, hyperglycemia, steroid psychosis, systemic infections
Dexamethasone	4–5 mg/kg/day IV			
	Pulses on alternate days × 6; once weekly × 8, fortnightly × 4, monthly × 8, bimonthly × 4 (abbreviated protocols also used)			Side effects of cyclophosphamide and prolonged steroid therapy
Prednisolone	Tapering doses × 18 months* PO			
Cyclophosphamide	2–2.5 mg/kg/day × 12 weeks** PO			

*Prednisolone 1.5 mg/kg on alternate days × 4 weeks; 1.25 mg/kg × 4 weeks; 1 mg/kg × 4 months; 0.5–0.75 mg/kg × 12–18 months.
**Cyclophosphamide is administered during 3–12 weeks.

following which the dose may be tapered. Prednisolone may be discontinued if the child is in sustained complete remission for 6–12 months.

Angiotensin converting enzyme inhibitors, angiotensin receptor blockers Therapy with angiotensin converting enzyme (ACE) inhibitors (e.g., enalapril 0.3–0.6 mg/kg/day, ramipril 6 mg/m^2/day) is associated with decrease in proteinuria and control of hypertension. Adverse effects include dry cough, hyperkalemia and decline in renal function. The dose of ACE inhibitor is decreased or therapy discontinued if hyperkalemia develops or eGFR falls less than 30 mL/minute/1.73 m^2. Angiotensin receptor blockers (e.g., losartan, valsartan) may be used in case of persistent dry cough with ACE inhibitors, or as add-on therapy for enhanced antiproteinuric effect. There are limited studies on the efficacy of this combination and it may be associated with significant toxicity.

Monitoring Response to Therapy
Patients should be monitored every month until response is demonstrated, and then every 2–3 months. *Complete remission* is defined as presence of trace or negative proteinuria (by dipstick) or spot urine protein to creatinine ratio (Up/Uc) less than 0.2 mg/mg. Patients are considered to be in *partial remission* if they show 1-2+ proteinuria (or Up/Uc between 0.2-2), blood albumin more than 2.5 g/dL and no edema. *Nonresponse* is defined as 3-4+ proteinuria (Up/Uc > 2), albumin less than 2.5 g/dL or edema. The aim of treatment is achievement of complete remission, but occurrence of partial remission is also satisfactory. Patients who respond to treatment do so within 3–6 months; those that fail therapy with one regimen may respond to different agents.

Monitoring for Adverse Effects of Drugs
Most agents used in the therapy of steroid resistance require monitoring for adverse effects. Monitoring for drug levels is recommended when using either cyclosporine or tacrolimus, because individual variations in bioavailability may result in occurrence of either subtherapeutic or toxic levels. A 12 hours trough level should be estimated about 2 weeks after introduction

of therapy, after any dose change, and if suspecting drug toxicity or poor compliance. Trough levels in the range of 80–120 ng/mL for cyclosporine and 4–7 ng/mL for tacrolimus are acceptable. Examination of renal histology is advised in patients receiving prolonged therapy (2–3 years) with calcineurin inhibitors. Histological features of nephrotoxicity include nodular hyalinosis or striped interstitial fibrosis and tubular atrophy. Prolonged duration of therapy (exceeding 2–3 year) and persistent heavy proteinuria (beyond 30 days) are risk factors for nephrotoxicity.

Duration of Therapy
Consensus is lacking on the optimal duration of treatment with calcineurin inhibitors. Therapy is continued for 2–3 years in patients that show complete or partial remission, followed by the options: (1) taper dose of the medication to the lowest effective dose, and continue for another 1–2 year; (2) exclude medication-related nephrotoxicity on renal histology and then continue therapy; (3) switch treatment to a less toxic agent, e.g., mycophenolate mofetil or rituximab.

Recurrence of FSGS after Renal Transplantation
Focal segmental glomerulosclerosis recurs in 30–50% of children following renal transplantation, leading to graft loss in half of these patients. Risk factors for recurrence are: (1) nongenetic forms of FSGS, (2) progression to end-stage renal disease within 2 years of onset of disease, (3) mesangial proliferation on original biopsies and (4) nephrectomy of native kidneys prior to transplant. Pretransplant plasmapheresis is an important preventive strategy. While there is no consensus on optimal therapy of patients with recurrent FSGS, options include: (1) intensive plasmapheresis; (2) high dose cyclosporine or tacrolimus; (3) rituximab; and (4) oral cyclophosphamide instead of mycophenolate mofetil.

CONGENITAL NEPHROTIC SYNDROME
Congenital nephrotic syndrome is defined as the presence of nephrotic syndrome within the first 3 months of life. While the Finnish type and other inherited defects are considered

the most common forms, its etiology is diverse, and includes: (1) Inherited mutations in genes encoding nephrin (*NPHS1*) (Finnish type); podocin (*NPHS2*) gene, phospholipase C epsilon 1 (*PLCE1* or *NPHS3*); Wilms tumor suppressor 1 (*WT1*) (Denys Drash syndrome; isolated nephrotic syndrome); laminin β2 (*LAMB2*) (Pierson syndrome; isolated nephrotic syndrome); laminin β3 (*LAMB3*) (Herlitz junctional epidermolysis bullosa); Lim transcription factor 1β (*LMXB1*) (nail-patella syndrome); (2) Galloway-Mowat syndrome (congenital nephrotic syndrome with microcephaly, developmental delay, hiatal hernia, diffuse mesangial sclerosis); (3) mitochondrial disorders; (4) primary FSGS; (5) congenital infections: syphilis, toxoplasma, malaria, cytomegalovirus, rubella, hepatitis B, human immunodeficiency virus; (6) maternal systemic lupus; and (7) maternal therapy with steroids and chlorpheniramine.

Clinical Features
Patients with congenital nephrotic syndrome present with edema at or soon after birth. Patients with the classical Finnish type of nephrotic syndrome are born premature, with large placentae, and wide cranial sutures and fontanelles. Failure to thrive, delayed development, hypothyroidism and repeated infections are noted. Common complications include hypotension (hypovolemia), spontaneous vascular thrombosis, hypertension and anemia (disease progression). Presence of associated abnormalities may suggest the diagnosis in infants with Galloway-Mowat syndrome (severe psychomotor retardation, hypotonia, and seizures), Pierson syndrome (microcoria) and Denys-Drash syndrome (ambiguous genitalia).

Evaluation
Investigations show nephrotic range proteinuria, low serum albumin (usually < 1 g/dL), elevated thyroid stimulating hormone and dyslipidemia. Renal function is normal but deranged in older infants and beyond infancy. Appropriate serology helps detect rare cases associated with congenital infections. Sequencing of *NPHS1* enables diagnosis of the Finnish nephrotic syndrome, also reported in individuals of non-Finnish ancestry. Mutations in other genes (*NPHS2*, *WT1* and *LAMB2*) might be important in patients of Asian ethnicity.

Histology
Renal biopsy shows microcysts in the cortex, representing dilatation of proximal convoluted tubules. Mesangial proliferation, thickened Bowman capsule and increase in mesangial matrix are common. Electron microscopy reveals effacement of foot processes, thin glomerular basement membrane, mild endothelial swelling and disappearance of the slit diaphragms. Histological changes may be absent if the renal biopsy is obtained early in the disease. The histology is evaluated in context of results of genetic testing; FSGS is common in patients with *NPHS2* mutations, while patients with mutations in *WT1, LAMB2* and *PLCE1* genes show diffuse mesangial sclerosis.

Management
Establishing the diagnosis is important for prognosis, therapy and genetic counseling. Management is difficult and outcomes are unsatisfactory. Immunosuppression has no role in managing infants with congenital nephrotic syndrome. Patients with congenital syphilis or toxoplasmosis may occasionally respond to appropriate antimicrobials. Control of edema requires the use of loop and thiazide diuretics, and frequent albumin infusions (20%, 1–4 g/kg/day, as required). Nutritional support is important to maintain well-being, and the diet should provide 120–130 Cal/kg/day and 3–4 g/kg/day proteins. Supplements of vitamins A, D, E and water-soluble vitamins, calcium and magnesium are provided. Nasogastric feeds may be necessary to ensure adequate intakes. A small dose of thyroxin (6.25–12.5 µg/day) is given, adjusted to TSH levels. Interventions that have been used to reduce proteinuria include: (1) ACE inhibitors (captopril 3–4 mg/kg/day or enalapril 0.2–0.5 mg/kg/day); (2) indomethacin (1–2 mg/kg/day); (3) unilateral or bilateral nephrectomy with institution of continuous peritoneal dialysis. Transplantation is offered once the body weight exceeds 9 kg.

Prognosis
Most affected children succumb to illness during infancy, either to infections or complications of the persisting nephrotic state. Children surviving past infancy show progressive kidney disease and require renal replacement therapy. Recurrent disease in the allograft is rare.

MEMBRANOPROLIFERATIVE GLOMERULONEPHRITIS
Membranoproliferative glomerulonephritis (MPGN) refers to a pattern of glomerular injury seen in a variety of diseases having in common, complement activation. The disease causes nephrotic syndrome usually in older children; other presentations include microscopic or gross hematuria with proteinuria, and rarely, rapidly progressive glomerulonephritis.

Classification
Light microscopy is characterized by diffuse mesangial cell proliferation and thickening of capillary walls due to subendothelial extension of the mesangium **(Fig. 1C)**. Based on findings on immunofluorescence and electron microscopy, two subtypes are recognized. Immune complex MPGN (previously type 1 MPGN) characterized by subendothelial immune complex deposits is secondary to activation of the classic complement pathway. Causes of immune complex MPGN include infections with hepatitis B or C viruses, lupus erythematosus, lymphoma, lipodystrophy and cryoglobulinemia. Evidence of activation of the classic complement pathway (normal or low serum C3, low C4) is present. C3 nephropathy (previously type II MPGN) is characterized by predominant presence of C3 deposits without significant immune complexes on immunofluorescence. Most patients have evidence of alternative pathway activation (markedly low serum C3, normal C4). A proportion of patients with C3 nephropathy show dense ribbon-shaped intramembranous deposits of C, in association with C3 nephritic factor, a circulating immunoglobulin that stabilizes C3 convertase resulting in persistent activation of the alternative complement pathway; others show factor H deficiency or dysfunction.

Management
The disorder is slowly progressive, with high-risk for renal failure particularly in C3 nephropathy. Factors indicating poor outcome are persistent heavy proteinuria, raised serum creatinine at the onset, presence of cellular crescents and tubulointerstitial disease. Long-term administration of alternate day prednisolone (1–1.5 mg/kg) combined with an angiotensin-converting enzyme inhibitor with or without mycophenolate mofetil may be useful. The role of eculizumab, a monoclonal antibody against C5, in interrupting complement activation is being investigated. Patients should be screened for hepatitis B and C infection before initiating immunosuppressive therapy. The majority of patients with dense deposit disease show recurrent illness in the transplanted kidney.

MEMBRANOUS NEPHROPATHY
Membranous nephropathy is an uncommon cause of nephrotic syndrome in childhood. Most cases are idiopathic, but the

disease may be secondary to lupus, infection with hepatitis B, Epstein-Barr virus, schistosomiasis and malaria, or exposure to medications (gold, penicillamine, nonsteroidal anti-inflammatory drugs). A majority of adult patients with idiopathic membranous glomerulonephritis (MGN) show autoantibodies to M type isoform of phospholipase A2 receptor; similar data in children is lacking. MGN is characterized by a diffuse thickening of the capillary basement membrane with subepithelial deposits and little or no cellular proliferation **(Fig. 1D)**. While in early stages light microscopy may be normal, IgG deposits are seen on immunofluorescence and in the subepithelial region on electron microscopy.

Management

Therapy with angiotensin converting enzyme inhibitors is effective in reducing proteinuria, and is recommended in all cases. Initial immunosuppressive regimen for primary MGN includes therapy with prednisolone and cyclophosphamide, failing which a calcineurin inhibitor (cyclosporine, tacrolimus) is recommended. A variable proportion of patients failing the above therapies respond to 2–4 doses of IV rituximab. Patients with hepatitis B-associated MGN may be treated with interferon-alpha and/or other antiviral agents.

SUPPORTIVE CARE AND MANAGEMENT OF COMPLICATIONS

Patients with relapsing steroid sensitive nephrotic syndrome and those with steroid-resistant disease require attention for complications resulting from disease or its therapy. Patients should be maintained in remission, as far as possible. Relapses should be promptly treated so that the child does not develop more than minimal edema.

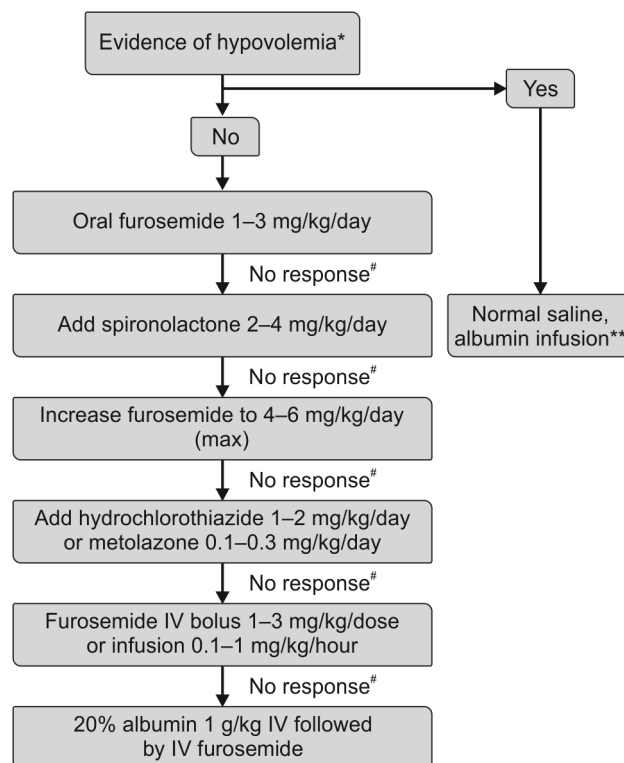
Edema

Presence of significant edema or anasarca is associated with discomfort and an increased risk of infections. Since daily administration of corticosteroids results in diuresis within 2–4 days, most patients do not require specific therapy for edema, particularly if urine protein is monitored at home. Those with significant edema and weight gain require treatment with diuretics.

Management

Edema is usually controlled with salt restriction and oral furosemide for a few days. **Flow chart 1** outlines the stepwise treatment of edema in children with nephrotic syndrome. Edema that does not respond to maximal doses of oral furosemide requires co-administration of thiazides (e.g., hydrochlorothiazide, metolazone). If furosemide is used for prolonged duration (> 7 days) or in high doses (3–6 mg/kg/day), use of spironolactone (2–4 mg/kg/day) prevents hypokalemia. Parents are instructed to discontinue diuretics if symptoms of hypovolemia (abdominal pain, dizziness) appear, or the child has diarrhea, vomiting or poor oral intake.

Patients with refractory edema should be hospitalized and administered IV furosemide either as boluses (1–3 mg/kg/dose IV over 15–20 minutes) or as continuous infusions (0.1–1 mg/kg/hour), under careful monitoring. Infusions of albumin (20% albumin, 0.5–1 g/kg, over 2–4 hours), with an IV bolus of furosemide, administered at the end of the infusion, are useful in patients with severe hypoalbuminemia. However, the effect is transient, requiring repeat administration in patients with severe edema. Care must be taken to avoid IV albumin in patients with oliguria, who may show worsening hypertension or congestive cardiac failure. Albumin administration should be avoided in individuals with oligoanuria and respiratory distress. Patients with refractory severe ascites and respiratory distress may require paracentesis, which should be done carefully under aseptic precautions. Hospitalized patients must be monitored carefully with daily record of weight and urine

Flow chart 1 Management of edema in patients with nephrotic syndrome


*Hypovolemia is suggested by the presence of tachycardia, feeble pulses, cold extremities or hypotension. Additional features include elevated hematocrit, disproportionately high blood urea, low fractional excretion of sodium (< 0.5%) and urinary $K^+/(K^+ + Na^+)$ more than 0.6. **Management of hypovolemia consists of rapid infusion of normal saline at a dose of 15–20 mL/kg over 20–30 minutes, repeated as required. Infusion of 5% albumin (10–15 mL/kg) or 20% albumin (0.5–1 g/kg) is useful in subjects who do not respond to two boluses of saline. #No weight loss or diuresis in 48 hours; or weight gain.

output, frequent monitoring of vital signs and daily estimation of electrolytes (hypokalemia, hyponatremia and metabolic alkalosis).

Hypovolemia

Hypovolemia may occur during severe disease relapse or following administration of diuretics, particularly in children with poor intake, diarrhea and vomiting. Features include abdominal pain, lethargy, dizziness and leg cramps, tachycardia, hypotension, delayed capillary refill, low volume pulses and cool clammy peripheries. An elevated ratio of blood urea to creatinine and rising hematocrit suggest the presence of hypovolemia. The level of urine sodium and its fractional excretion are reduced to less than 20 mEq/L and 0.2–0.4% respectively. A high urinary potassium index, urine $K^+/(urine K^+ + Na^+)$ exceeding 0.6 suggests presence of hypovolemia.

Therapy with diuretics should be discontinued. When signs of hypovolemia are absent, an increase in oral fluid intake alone may suffice. With features of hypovolemia, patients require admission and rapid infusion of normal saline (10–20 mL/kg) over 20–30 minutes. Patients who do not respond to two boluses of saline should receive infusion of 5% albumin (10–15 mL/kg) or 20% albumin (0.5–1 g/kg).

Infections

Common infections include peritonitis and cellulitis, which should be treated using appropriate antibiotics. Complications of varicella

may be life-threatening in patients with nephrotic syndrome receiving corticosteroids or other immunosuppressive drugs. All patients with varicella must receive oral acyclovir for 7 days; severe illness requires admission and administration of IV acyclovir. Administration of varicella zoster immunoglobulin (single dose within 96 hours of exposure), or intravenous immunoglobulin (400 mg/kg, single dose) prevents or lessens the severity of the disease in susceptible individuals.

Hypertension

Hypertension may be noted at the onset of disease or develop secondarily as a result of high dose steroid therapy. Persistent elevation in blood pressure, refractory to control of edema and decline of corticosteroid dose, merits treatment. An angiotensin converting enzyme inhibitor, enalapril (0.3–0.6 mg/kg/day in two divided doses) or ramipril is the medication of choice. The dose is increased to permissible limits in patients with persistent hypertension, while monitoring renal function and levels of potassium. Some patients require additional therapy with calcium channel blockers (e.g., amlodipine) or adrenergic blockers. The target blood pressure is between the 75th percentile and 90th percentile for age, gender and height.

Dyslipidemia

Patients with steroid-resistant nephrotic syndrome with persistent proteinuria have continued dyslipidemia that is undesirable, and requires treatment. Therapy with HMG-CoA reductase inhibitors (atorvastatin 10–20 mg daily in children greater than 5 years) is recommended in presence of biochemical abnormalities that persist for 3–6 months: total cholesterol more than 200 mg/dL or low-density lipoprotein cholesterol more than 130 mg/dL.

Thrombosis

Children with nephrotic syndrome are predisposed to venous thromboembolism during relapses, due to multiple reasons including loss of antithrombin III, low intravascular volume (aggressive diuretic use, diarrheal dehydration), immobilization, indwelling catheters and puncture of deep vessels. Thrombosis should be suspected in patients with hematuria or flank pain (renal vein thrombosis); venous congestion, pain, reduced mobility of limbs (deep vein thrombosis); or seizures, vomiting, altered sensorium and neurological deficits (sagittal sinus or cortical venous thrombosis). Diagnosis requires confirmation with ultrasonography, Doppler studies and cranial MRI if required. Therapy includes use of heparin or low-molecular-weight heparin initially, followed by oral anticoagulants for 4–6 months.

Vaccination

Administration of live vaccines (oral polio, varicella) should be deferred until the child is off immunosuppressive medications for at least 4 weeks. If essential, these vaccines may be given to patients receiving alternate day prednisolone at a dose less than 0.5 mg/kg. The administration of pneumococcal vaccine is desirable. Children below 2 years of age should receive the pneumococcal conjugated vaccine, 0.5 mL intramuscularly, in the schedule advised by the Indian Academy of Pediatrics. Above 2 years, one dose of the polysaccharide vaccine (PPV23) is administered, following one dose of the conjugate vaccine; the gap between the injections should be at least 2 months. Children who continue to have relapses of nephrotic syndrome may receive one repeat dose of PPV23, 5 year after the primary vaccination.

Two doses of the varicella vaccine are given 4 weeks apart while the child is in remission and off immunosuppressive medications. Injectable polio vaccine may be given to children with nephrotic syndrome and their siblings. If the child has received primary immunization with oral polio vaccine (6, 10 and 14 weeks), two doses of parenteral vaccine are given at 2 months interval followed by a third dose 6 months after the first dose, and a booster at 5 years.

Nutrition

During remission, children should eat a balanced, nutritious diet without restrictions. If relapses are associated with edema, salt restriction is advised, by curbing the intake of snacks and foods with high salt content. Undue restriction that makes food unpalatable is not required. Patients with persistent or recurrent proteinuria should increase their intake of proteins to 2–2.5 g/kg/day. Increase in physical activity can help achieve desirable body weight in those with Cushingoid features or obesity. Patients on prolonged therapy with prednisolone (> 3 months) should receive supplements of calcium carbonate (250–500 mg) and vitamin D (125–250 IU).

Stress Dose of Steroids

Patients who have received steroids at high doses for more than 2 weeks in the past year are at risk of suppression of the hypothalamo-pituitary-adrenal axis. These children require steroid supplements during surgery, anesthesia or serious infections. Corticosteroids are supplemented, as parenteral hydrocortisone at a dose of 2–4 mg/kg/day, followed by oral prednisolone at 0.3–0.6 mg/kg/day. This is given for the duration of stress and then tapered rapidly.

The long-term management of nephrotic syndrome requires frequent interactions with patients' families to ensure their cooperation in disease management. Parents are explained the natural history of the disease and its outcome, and the expected adverse effects of repeated courses of high dose steroid therapy and other medications. While steroid responsiveness remains the most important prognostic feature, patients with both steroid sensitive and steroid-resistant disease require close monitoring of disease course and timely management of disease and therapy-related complications in order to enable satisfactory long-term outcomes.

IN A NUTSHELL

1. Nephrotic syndrome is the most common chronic kidney disease of childhood. The majority (85–90%) is steroid responsive; minimal change nephrotic syndrome accounts for more than 75% cases.
2. The precise cause of idiopathic nephrotic syndrome is unclear, but has been attributed to aberrant immune system with Th2 predominance and/or downregulation of T regulatory axis. Others suggest a primary defect in the podocyte slit diaphragm or actin cytoskeleton; mutations in a number of genes encoding podocyte proteins have been described. The role of circulating mediators that affect glomerular permeability is being examined.
3. Steroid responsiveness is the chief prognostic factor that determines long-term outcomes.
4. In patients with steroid sensitive nephrotic syndrome, prudent use of corticosteroids and steroid sparing agents is recommended to avoid side effects of therapy and complications associated with the illness.
5. Calcineurin inhibitors are the drugs of choice for patients with steroid-resistant nephrotic syndrome. Patients with steroid resistance who fail to respond to the above therapy are at risk for progressive renal disease.
6. Common complications of nephrotic syndrome include life-threatening infections (peritonitis, cellulitis), thrombotic events, hypovolemia, progressive renal failure and side effects of immunosuppressive agents.

Chapter 41.11
Acute Kidney Injury
Anil Vasudevan

Acute kidney injury (AKI), formerly known as acute renal failure is characterized by an abrupt (48 hours to 7 days) and sustained decline in glomerular filtration rate (GFR) and an inability of kidneys to appropriately regulate fluid, electrolytes and acid-base homeostasis. The spectrum of injury ranges from mild to advanced, sometimes requiring renal replacement therapy (RRT). AKI is associated with significant mortality and morbidity, especially in critically ill children. Although the precise incidence in children is not known, data indicate that its incidence is increasing. The etiology of AKI has changed from primary renal disease to multifactorial causes, particularly in hospitalized children.

DEFINITION

The definition of AKI is based on level of serum creatinine and urine output. The current definition and staging of patients with AKI is summarized in **Table 1**. While these definitions have been validated in adults, there is limited data in this regard for children. Although, useful for stratifying children based on severity of illness, there are limitations in the classification. Serum creatinine rises only after 25–50% of kidney function is lost. Besides, creatinine cannot be used to assess kidney function in patients receiving dialysis or in the first few days of life (when they reflect maternal creatinine). Nonoliguric AKI is common in neonates, and hence the urine output criteria might not hold in case of newborns.

EPIDEMIOLOGY

The incidence of AKI varies in different regions of the world; estimates range from 20 cases per year per 100,000 population in neonates to as low as two cases per year per 100,000 population in older children. The coexistence of AKI with critical illness occurs at a rate of 10% and has 50% mortality in children requiring dialysis. A study from a tertiary care center in north India, reported incidence densities of 45.1 and 11.7 AKI cases/1,000 patient days in critically ill and noncritically ill children respectively. The incidence of AKI in critically ill neonates is estimated to be between 8% and 24% and that mortality rates are between 10% and 61%. It is recognized that AKI characteristics and etiology in developing countries differs from that of the developed world is many important ways. AKI is the disease of the young and children in whom volume responsive *prenal* mechanisms are common. *Community acquired* AKI

Table 1 Criteria for diagnosis and staging of acute kidney injury

Stage	Serum creatinine	Urine output
I	Increase ≥ 0.3 mg/dL in < 48 hours, or 1.5–1.9 times increase over 7 days	< 0.5 mL/kg/hour for 6–12 hours
II	Increase 2.0–2.9 times	< 0.5 mL/kg/hour for ≥ 12 hours
III	Increase ≥ 3 times, or > 4.0 mg/dL, or initiation of renal replacement therapy, or if < 18-year-old: eGFR < 35 mL/min/1.73 m^2	< 0.3 mL/kg/hour for ≥ 24 hours, or anuria for ≤ 12 hours

eGFR estimated glomerular filtration calculated using Schwartz formula:
$$\frac{0.43 \times \text{height (cm)}}{\text{Serum creatinine (mg/dL)}}$$

forms a significant proportion of cases, compared to the developed world where *hospital acquired AKI* dominates.

ETIOLOGY, RISK FACTORS AND PATHOPHYSIOLOGY

The underlying causes of AKI are divided into prerenal azotemia, renal injury and postrenal obstruction. In most cases, the true etiology is likely multifactorial, related to a combination of several factors (e.g., hypotension, use of nephrotoxic agents and sepsis). **Table 2** lists common causes of AKI in children. Common causes of AKI in our country are volume loss leading to ischemic renal injury, infections and hemolytic uremic syndrome. In developed countries, most AKI is related to sepsis, use of nephrotoxic agents and renal ischemia (postoperative, bone marrow transplant). AKI in the critical care setting is caused by secondary renal injury rather than primary disease, characteristically acute tubular necrosis. Young age, presence of comorbidities (chronic kidney disease, cardiac disease, liver failure), use of nephrotoxic agents [nonsteroidal anti-inflammatory drugs (NSAIDs), aminoglycosides, radiocontrast agents], children receiving stem cell transplants and those undergoing cardiopulmonary bypass are risk factors for AKI. Newborns are particularly at risk as they are susceptible to hypoperfusion, low GFR and might be exposed to nephrotoxic medications and frequent infections. Neonates with hypoxic encephalopathy and those undergoing cardiopulmonary bypass are at high-risk.

Prerenal Acute Kidney Injury

Prerenal azotemia is characterized by diminished effective circulating arterial volume, which leads to inadequate renal perfusion and decreased GFR. Hypovolemia resulting in low renal blood flow activates the autoregulatory mechanisms so as to preserve GFR. The compensatory mechanisms that are triggered include increasing renal sympathetic tone, activation of the renin-angiotensin-aldosterone system, and increased activation of hormones such as vasopressin and endothelin resulting in afferent arteriolar dilatation and efferent arteriolar constriction to maintain the glomerular pressure gradient. These mechanisms enhance proximal tubular sodium and water reabsorption and urea in those with intact tubular function leading to decreased water and sodium losses which help in maintaining systemic volume and blood pressure. If volume is restored, the renal function abnormalities are reversible.

Acute Tubular Necrosis

Acute tubular necrosis (ATN), characterized by renal tubular injury may occur due to ischemia/hypoperfusion or due to injury from drugs or toxins **(Table 2)**. Ischemic ATN is a continuum of physiologic responses that is observed in prerenal azotemia. It is characterized by parenchymal damage, chiefly affecting the medullary S3 segment of the proximal tubule and medullary portion of the thick ascending limb of Henle. If ischemia/hypoperfusion is severe and prolonged, ATN can progress to renal infarction and corticomedullary necrosis with irreversible renal damage. Pathophysiologically, the course of ischemic AKI may be subdivided into four phases: initiation (decrease in perfusion and depletion of ATP), extension (ischemia reperfusion injuries aggravating tubular injury), maintenance (tubular injury persists due to persistence of inflammation) and recovery (repair and regeneration of tubular cells). The initiation phase includes the primary insult resulting in a drop in GFR and the tubular dysfunction. The duration of the maintenance phase depends on the severity and duration of the initial insult. These phases are characterized by oligoanuria. The recovery phase is characterized

Table 2 Etiology of acute kidney injury

Prerenal	Renal	Postrenal
Decreased true intravascular volume	*Glomerular*	*Obstructive uropathy*
Severe diarrhea, vomiting	Postinfectious glomerulonephritis	Ureteropelvic
Burns	Crescentic glomerulonephritis	junction obstruction
Hemorrhage, trauma	*Vascular lesions*	Bilateral ureteral
Sepsis	Hemolytic uremic syndrome	obstruction
	Cortical necrosis	Urethral obstruction
Decreased effective intravascular volume	Renal vein or artery thrombosis	Posterior urethral
Anaphylaxis		valves
Septic shock	*Acute tubular necrosis*	
Dengue hemorrhagic fever	*Endogenous toxins:* Intravascular hemolysis, rhabdomyolysis,	*Nephrolithiasis*
Cardiac failure	tumor lysis syndrome	*Neurogenic bladder*
	Exogenous toxins: Ethylene glycol, methanol	
Medications	*Drugs:* Nephrotoxic agents	
Indomethacin	Hypoxic ischemic insult	
Angiotensin converting enzyme inhibitors		
Angiotensin receptor blockers	*Acute tubulointerstitial nephritis*	

by restoration of GFR and tubular functions and manifests with polyuria initially, after which the urine output returns to normal. Complete recovery may take months when the initial insult is severe.

Infection-associated Acute Kidney Injury

Sepsis is a leading cause of AKI in children. Based on various experimental studies in animal models, understanding of sepsis-associated AKI pathophysiology is shifting from renal vasoconstriction, ischemia, and acute tubular necrosis to inflammatory mediator effects on renal vascular endothelium and microcirculatory dysfunction characterized by unbalanced homeostasis between nitric oxide, reactive oxygen species and renal oxygenation.

Malaria may present either as AKI alone or as part of a multiorgan dysfunction. Volume depletion, gastrointestinal bleeding, sepsis, nephrotoxic drugs and hyperbilirubinemia act as predisposing factors. The pathogenesis of AKI is not clearly known. Different hypotheses proposed include hypovolemia, cytokine and nitric oxide-mediated arterial vasodilatation, resistance to vasoactive hormones, cytopathic hypoxia leading to decreased ATP synthesis and mechanical obstruction by infected erythrocytes (cytoadherence). Renal histology consistently shows ATN and interstitial nephritis and glomerulonephritis (GN) may also be seen.

The incidence of AKI in severe leptospirosis varies from 40% to 60%. Clinical manifestations are biphasic, with an initial septicemic phase lasting 3–7 days followed by an immune phase, during which nephropathy occurs. The pathogenetic mechanisms include bacterial invasion, inflammatory processes, hemodynamic alterations and toxicity of bacterial products. AKI in leptospirosis is primarily nonoliguric, and hypokalemia occurs frequently due to kaliuresis; histology shows interstitial nephritis. Leptospirae may be detected in the urine between 1 week and 4 weeks of infection, using dark-field illumination.

Snakebite Envenomation

Snakebites are serious in children because of the relatively large volume of venom injected. Snakes belonging to the families Elapidae, Viperidae, Colubridae and Hydrophiidae cause AKI. Clinical presentations include proteinuria, hematuria, pigmenturia, rhabdomyolysis and myoglobinuria. Kidney injury occurs within a few hours to as late as 96 hours after the bite and is oligoanuric in 94% patients. ATN, with varying degrees of interstitial edema and inflammatory cell infiltration, is the most common histology. Direct nephrotoxicity, hypovolemia, hemolysis, myoglobinuria and disseminated intravascular coagulation are the usual pathogenic mechanisms.

Tumor Lysis Syndrome

Tumor lysis syndrome is seen in patients undergoing first cycle of chemotherapy when rapid tumor destruction occurs, such as in acute myeloid leukemia and lymphomas. Biochemical abnormalities include hyperkalemia, hyperphosphatemia, hyperuricemia and hypocalcemia. The precipitation of uric acid crystals in the tubules causes occlusion and decreased filtration.

EVALUATION AND DIAGNOSIS

Clinical features range from asymptomatic with mild to moderate elevation in serum creatinine to anuric renal failure **(Box 1)**. Combining the information from detailed history and physical examination and laboratory investigations can help in identifying the probable casue of AKI. A key part of the evaluation is to identify reversible causes (obstruction, drug-induced AKI).

History and Examination

Edema, hematuria and hypertension suggest a glomerular cause of AKI. History of pyoderma or acute pharyngitis preceding the onset of hematuria, edema and oliguria by few weeks suggests a postinfectious GN. A critically ill child with fever, jaundice, and pallor and hepatosplenomegaly may have AKI secondary to malaria or leptospirosis. Rash or arthritis may suggest vasculitis. A child with history of dysentery and who subsequently develops pallor, petechiae and oliguria is likely to be hemolytic uremic syndrome. A history of interrupted or poor urinary stream with a palpable bladder suggests obstructive uropathy.

A detailed fluid balance history in addition to a history of diarrhea, vomiting, blood loss helps determine the extent to which renal hypoperfusion may be contributing to AKI. Urine

BOX 1 Clinical features of acute kidney injury

- *Decrease or no urine output:* Oliguria < 1 mL/kg/hour; anuria < 0.5 mL/kg/hour
- *Fluid overload:* Edema, tachypnea, abdominal pain, respiratory distress
- *Hypertension:* Headache, vomiting, blurring of vision, seizures
- *Uremia, dyselectrolytemia:* Nausea, vomiting, altered sensorium, encephalopathy, seizures.

output estimation, from history or by quantification, identifies patients with oliguric, anuric or normal urine output and provides clue to the underlying cause. Nonoliguric AKI is seen with toxin or medication-mediated ATN. Anuria is seen in children with urinary tract obstruction, renal cortical necrosis [snake bite, disseminated intravascular coagulation, hemolytic uremic syndrome (HUS)], bilateral renal vein thrombosis and severe dehydration. Information on urine output also help evaluate whether a positive fluid balance is occurring, which suggests that prerenal injury has progressed to cause intrinsic renal injury. Detailed medication history will elucidate its role in mediating AKI (NSAIDs, aminoglycosides, chemotherapeutic agents, angiotensin converting enzyme inhibitors, or radiocontrast agents).

Investigations

Laboratory tests are useful for assessing the etiology and complications of AKI, and management of the disease **(Box 2)**. Urinalysis should be obtained in all children with AKI as it is an informative and noninvasive diagnostic tool. In prerenal AKI, the urine is *bland* with a high specific gravity reflecting appropriate renal retention of water in the setting of renal hypoperfusion. With intrinsic injury, the urine may show mild hematuria and/or proteinuria with a specific gravity 1.015 or less with presence of granular or muddy brown casts and renal tubular epithelial cells. With glomerular injury, the amount of hematuria and proteinuria is moderate to severe. The presence of white blood cells (WBC) or WBC casts suggests pyelonephritis or acute interstitial nephritis. Presence of uric acid crystals or oxalate crystals suggests uric acid nephropathy and ethylene glycol toxicity respectively. While urinary indices may be used to differentiate prerenal from intrinsic renal failure, these indices are not helpful in children who have received diuretics and those with chronic kidney disease or tubular disorders **(Table 3)**.

Imaging

Renal ultrasonography should be performed in children with AKI to rule out obstruction of the urinary collecting system. In intrinsic AKI, the imaging shows increased echogenicity and loss of corticomedullary differentiation of the kidneys. Noncontrast computed tomography may be indicated for evaluation of obstructive AKI (stones, tumor).

Renal Biopsy

Renal biopsy has proven useful in diagnosis and prognostication of select cases (e.g., rapidly progressive GN, hemolytic uremic syndrome, drug-induced AKI) and in children in whom etiology of AKI is not identified particularly in context of systemic disease.

BOX 2 Laboratory investigations in acute kidney injury

Routine
- Urinalysis
- Complete blood counts
- Blood urea, creatinine, electrolytes, calcium, phosphate
- Blood pH, bicarbonate, chloride, carbon dioxide tension
- Chest X-ray
- Ultrasonography of kidneys and genitourinary tract

Specific situations
- Reticulocyte count, haptoglobin, lactate dehydrogenase
- Creatine phosphokinase
- Complement C3 levels, antistreptolysin
- Antinuclear antibody
- Antineutrophil cytoplasmic antibody
- Antiglomerular basement membrane antibody
- Hepatitis B surface antigen; hepatitis C serology.

Table 3 Urinary indices to distinguish prerenal from intrinsic acute kidney injury

	Prerenal	*Intrinsic renal*
Specific gravity	> 1.020	< 1.010
Urinary osmolality (mOsm/kg)	> 500	< 300
Urine Na (mEq/L)	< 20	> 40
Fractional excretion of sodium (%)	< 1	> 1
Blood urea nitrogen/creatinine	> 20:1	< 20:1

Biomarkers for Early Diagnosis of AKI

Diagnosis of AKI relies on estimation of renal function by serum creatinine level which has many limitations. Serum creatinine concentrations do not change until significant injury and loss of renal function has occurred. Besides, serum creatinine levels can vary with muscle mass and with different methods of measurement used in laboratories. This has led to interest in the discovery and validation of novel AKI biomarkers in serum and urine for early diagnosis and to estimate severity of AKI **(Table 4)**. However, the routine use of the biomarkers in the clinic are limited as they have not been integrated with creatinine and urine output changes to enhance management of AKI. These noninvasive biomarkers of AKI have only been tested in small subsets of the critically ill neonates and hence the utility of these biomarkers has not been established. To ensure judicious use of biomarkers, it is important that children *at risk* for AKI are identified. Renal angina index (RAI) has found to be useful for prediction of severe AKI. The RAI consists of three risk factors (PICU admission, ventilation or use of ionotropes, and organ transplant) and two markers of renal injury (change in GFR from baseline and percent fluid overload) which are assigned points. The score can range from 1 to 40; score more than 8 predicts severe AKI.

MANAGEMENT

Management of AKI includes optimizing renal perfusion pressure and oxygenation and treating associated complications, while ensuring nutrition and avoidance of additional nephrotoxins.

Maintenance of Fluid Balance

Fluid and electrolyte prescription depends on the volume status of the patient. Blood pressure, heart rate, skin turgor, capillary refill and mental status are used to assess the intravascular volume. Children who are severely dehydrated are likely to be in prerenal azotemia. Fluid resuscitation with 10–20 mL/kg normal saline boluses (maximum 60–80 mL/kg) to re-establish intravascular volume is warranted. Further boluses are given if hypovolemia persists. Normal saline is the preferred choice of fluid for volume expansion. Use of artificial colloids like hydroxyethyl starch should

Table 4 Serum and urinary biomarkers in acute kidney injury

	Early detection	*Need for renal replacement therapy*	*Death*
Serum	NGAL, cystatin C, Pro-ANP	NGAL, cystatin C	
Urine	NGAL, IL-18, KIM-1, γ-GT, NAG, MMP-9	NGAL, cystatin C, NAG, KIM-1, α1 microglobulin, β2 microglobulin	NGAL, IL-18, KIM-1

Abbreviations: ANP, atrial natriuretic peptide, γ-GT, glutamyltransferase, IL, interleukin, KIM-1, kidney injury molecule-1, MMP-9, matrix metalloproteinase-9, NAG, N-acetyl-β-d-glucosamide, NGAL, neutrophil gelatinase associated lipocalin.

be avoided as there are indications of an increased risk of AKI. If there is no urine output, furosemide 2 mg/kg IV is given.

Children with prerenal azotemia who do not pass urine after adequate fluid resuscitation or children with normal intravascular volume and oliguria are likely to have intrinsic AKI. The fluids prescribed should be restricted to insensible losses (400 mL/m^2/24 hour) plus replacement of urine output and extrarenal losses (gastrointestinal losses due to diarrhea and vomiting). Children receiving mechanical ventilation require lower insensible loss volume replacement. The replacement of all or only part of extrarenal losses depends on the clinical situation. Urinary and insensible losses are replaced with 0.45% saline and 5% dextrose respectively. Children with fluid overload may be managed with replacement of insensible losses plus replacement of half of urine output and extrarenal losses. Those with overt fluid overload will require dialysis in addition to fluid restriction. Patients with polyuric AKI such as aminoglycoside toxicity are given appropriate fluid and electrolyte replacement based on urine output and serum electrolytes.

Ongoing fluid therapy is guided by daily weights, blood pressure, fluid input and output records, physical examination, nutritional needs of the child and serum electrolytes. In critically ill children, central venous pressure monitoring may be necessary to guide fluid therapy. Attention to fluid balance in critically ill children is necessary to prevent fluid overload, since presence of AKI increases ICU mortality, at least in part due to fluid retention.

Cumulative fluid overload:

$$\frac{\text{Fluid input (L) – fluid output (L)}}{\text{ICU admission weight (kg)}} \times 100$$

If the child has more than 10% fluid overload, evaluation for renal support therapy should occur and if overload is more than 20%, initiation of renal support therapy should be strongly considered. In children with oligoanuric renal failure, potassium containing fluids should not be given unless they are severely hypokalemic.

Treatment of Complications

Hyperkalemia, dysnatremias, hypertension, metabolic acidosis and anemia are complications in children with AKI, which should be recognized and treated promptly **(Table 5)**.

Nutritional Support

Acute kidney injury can be associated with severe anorexia, and child may be at risk for malnutrition when AKI is prolonged. Child

should receive appropriate maintenance calories and proteins. The requirement may be higher in children with hypercatabolic state. If sufficient calories cannot be achieved while maintaining appropriate fluid balance, early initiation of dialysis is considered.

Treatment of Underlying Cause

Prompt recognition and management of underlying cause for AKI is important in limiting the severity of AKI **(Box 3)**.

Pharmacologic Therapy

Diuretics and *renal-dose* dopamine (5 μg/kg/min) are commonly used to prevent or limit AKI. Meta-analyses have confirmed that renal-dose dopamine has no benefit and may even be harmful. The main indication for use of diuretics is management of volume overload. Diuretics may increase the urine output thereby allowing easier management of fluid balance. In absence of fluid overload, the conversion of oliguric to nonoliguric AKI using diuretics does not improve morbidity, mortality, or renal outcomes. While there are no current specific therapy to promote recovery in human AKI (specifically ATN), several potential therapies are being studied (e.g., melanocyte-stimulating hormone, insulin-like growth factor-1 radical scavenger and antioxidants, mesenchymal stem cells, and erythropoietin).

Drug Dosing in Acute Kidney Injury

Prescribing medications in AKI requires attention as many drugs are metabolized and/or excreted by kidneys. The dose and frequency of administration of drugs should be adjusted for the degree of renal failure, based on the GFR (GFR > 50 mL/min/1.73 m^2, 20–50 mL/min/1.73 m^2, or < 20 mL/min/1.73 m^2). Drugs that

---

BOX 3 Management of specific causes of acute kidney injury

- Withdrawal, replacement of medication (aminoglycosides, nonsteroidal anti-inflammatory drugs)
- Antimicrobial therapy (malaria, leptospirosis, sepsis, urinary tract infection)
- Surgical intervention for obstruction (removal of stones)
- Diuretics and alkalinization of urine (crush injury, myoglobinuria, hemoglobinuria)
- Plasmapheresis (atypical hemolytic uremic syndrome, rapidly progressive GN, vasculitis)
- Immunosuppression (rapidly progressive GN, vasculitis, autoimmune thrombotic microangiopathy).

Table 5 Management of complications of acute kidney injury

Complication	Treatment
Hypertension	*Symptomatic*: Nitroprusside 1–8 μg/kg/minute infusion; labetalol 0.25–3 mg/kg/hour; furosemide 2–4 mg/kg IV if fluid overload *Asymptomatic*: Nifedipine 0.3–0.5 mg/kg PO
Metabolic acidosis	Sodium bicarbonate (IV, oral) based on severity; refractory acidosis may require dialysis
Hyperkalemia	*Emergency*: Calcium gluconate (10%) 0.5–1 mL/kg over 5–10 minutes Salbutamol 5–10 mg nebulized *Less urgent*: Glucose (50%) 0.5–1 g/kg with 0.1–0.2 units/kg insulin Sodium bicarbonate (8.4%) 1–2 mL/kg over 15–20 minutes Calcium resonium 1 g/kg/dose 8 hours *Refractory:* May require dialysis
Hyponatremia	*Fluid overload*: Restrict fluids *Sensorial alteration or seizures*: 3% saline 5 mL/kg over 30–90 minutes
Hypocalcemia	IV 10% calcium gluconate (1 mL/kg, maximum 10 mL) over 30 minutes under cardiac monitoring
Hyperphosphatemia	Phosphate binders (calcium carbonate, acetate); dietary phosphorus restriction

are nephrotoxic (aminoglycosides, NSAIDs, radiocontrast agents, vancomycin) should be avoided.

Renal Replacement Therapy

The indications to initiate RRT are not absolute and are determined by a number of factors, including the underlying cause, patient age, rapidity of renal failure and fluid and electrolyte abnormalities **(Box 4)**. The goals are to correct metabolic abnormalities, restore and maintain fluid and electrolyte balance, and maintain the physiological milieu. RRT is provided by peritoneal dialysis, intermittent hemodialysis or continuous RRT. These modalities have advantages and limitations, and comparisons of modalities is difficult. The choice of modality is determined by multiple factors: clinical situation, age and patient size, hemodynamic status, availability of resources and expertise, and the cost of therapy.

OUTCOMES

Acute kidney injury is an independent risk factor for mortality with children dying *from* and not just *with* renal failure. The mortality rates in critically ill children with AKI are high, ranging between 10% and 60% with a higher proportion in those with severe AKI and if complicated by multiorgan failure. In addition, 10–25% patients with AKI may develop chronic kidney disease. Children who survive an episode of AKI should be followed-up long-term with monitoring of blood pressure, urinalysis and measurement of serum creatinine. The prognosis of AKI is dependent on the underlying etiology of the AKI. Children with primary renal disease (acute GN, acute interstitial nephritis, diarrhea-related HUS) have lower mortality compared to children who develop AKI due to multifactorial causes (critically ill). ATN due to ischemia or nephrotoxins has favorable outcomes. Prognostic factors include age of the child, duration and severity of anuria and AKI, need for RRT, fluid overload and severity of illness at time of admission.

IN A NUTSHELL

1. Acute kidney injury is an important contributor to mortality and morbidity in critically ill children. Pediatric RIFLE, AKIN and KDIGO criteria are available to define and stage AKI.
2. Volume depletion due to acute gastroentritis, infections like malaria, leptospirosis, dengue and hemorrhagic fever, snake evenomation and HUS are common causes of AKI in children.
3. In critically ill children, causes of AKI include sepsis, multiorgan dysfunction, trauma and organ transplantation.
4. Ultrasonography is a sensitive investigation to identify obstructive cause of AKI.
5. Biomarkers in serum and urine are useful for early diagnosis, but their utility is not been proven.
6. Life-threatening complications are pulmonary edema, hypertensive encephalopathy, hyponatremia, hyperkalemia and severe metabolic acidosis.
7. There are no specific drugs to treat AKI; supportive care is the cornerstone of management.
8. Indications for RRT are not absolute and are determined by a number of factors. RRT may be provided by peritoneal dialysis, intermittent hemodialysis, or continuous RRT.
9. Patients who survive AKI should be followed-up for chronic kidney disease.

Chapter 41.12
Renal Replacement Therapy for Acute Kidney Injury
Sidharth Kumar Sethi, Rupesh Raina

Provision of renal replacement therapy (RRT) to children requires special considerations as compared to adult patients. The weight varies from a few hundred grams in extremely low birthweight babies to over 100 kg in obese adolescents. The etiology of acute kidney injury (AKI) varies (*See* Chapter 41.11). Optimal care of the patients with severe AKI involves an understanding of the features of multiorgan dysfunction syndrome, and the local availability of RRT modalities and expertise.

INDICATIONS

Multiple retrospective studies in critically ill children have that AKI and multiorgan dysfunction syndrome develop early and are associated with increased mortality and prolonged ICU stay. Early provision of RRT in these children may prevent life-threatening complications of uremia, fluid overload and dyselectrolytemia. Indications of RRT are listed in previous chapter. However, these criteria are relatively late manifestations of renal dysfunction, and most physicians are inclined to initiate RRT relatively early in critically sick children. Information from prospective series show that fluid overload in critically ill children is an independent predictor of mortality. Early initiation of RRT also provides room for parenteral nutrition and/or blood products while preventing fluid overload.

CLASSIFICATION

The available modalities for RRT function chiefly using one or more of the following physiological mechanisms: (1) Diffusion: Solute exchange across a semipermeable membrane, governed principally by concentration gradient, solute size and charge; (2) Ultrafiltration: Movement of water across a membrane primarily by hydrostatic pressure (in hemodialysis and hemofiltration) or along an osmotic agent (peritoneal dialysis); and (3) Convection: Solute transfer along with ultrafiltration across a semipermeable membrane, occurring independent of the concentration gradient. Various modalities for RRT are classified on the basis of these mechanisms. Based on the duration, therapies are classified as intermittent or continuous, where duration of each intermittent therapy is less than 24 hours, whereas for continuous therapy is at least 24 hours. Hemodialysis is an intermittent therapy, even when prolonged beyond the standard 4 hours prescription, as during sustained low efficiency dialysis and extended daily dialysis.

CHOICE OF MODALITY

The choice of dialysis modality depends on patient and organizational characteristics.

Patient Characteristics

Desired goal of dialysis If the patient just requires fluid removal, any of the modalities, including peritoneal dialysis, hemodialysis or slow continuous ultrafiltration may be used, based on the child's hemodynamic status and institutional preferences.

Size Putting a double lumen hemodialysis catheter in neonates may be technically difficult and not achieve adequate flows. In these situations, peritoneal dialysis is a viable option.

Urgency of solute clearance Conditions associated with rapid solute generation and need for urgent fluid removal, such as tumor lysis syndrome, hyperammonemia, symptomatic hyperkalemia and ingestion of a dialyzable toxin, are indications where relatively efficient modalities like hemodialysis or continuous RRT (CRRT) are preferred over peritoneal dialysis.

Hemodynamic status CRRT may be the only suitable options for critically ill children with sepsis and multiorgan dysfunction with shock requiring inotropes; postoperative infants, e.g., following cardiopulmonary bypass, may be managed on peritoneal dialysis.

Coexistent coagulopathy: Attainment of vascular access and use of anticoagulation for hemodialysis or CRRT are risky in presence of prolonged bleeding or prothrombin time or thrombocytopenia.

Organizational Characteristics

Peritoneal dialysis is preferred in resource constrained areas, while hemodialysis or CRRT are used as primary modalities in units with available expertise. The preference may depend on the finances, unit preference or staff training and expertise.

Peritoneal Dialysis

Peritoneal dialysis is the most widely used RRT in the world, especially in centers with limited resources. Because of its simplicity, safety and relative ease, the procedure can be performed in very small patients. The technique has minimal serious hemodynamic consequences and does not require vascular access, often the limiting factor in initiating dialysis in small infants.

Catheters

Catheters used commonly for acute dialysis in infants and children are the noncuffed rigid acute catheter and the surgically placed cuffed silicone Tenckhoff catheter. Once inserted, a stiff catheter can be used safely for a maximum of 72 hours, beyond which there is an increasing risk of peritonitis. Tenckhoff catheters are preferred when anticipating prolonged dialysis.

Prescription

The prescription of dialysis is individualized to the clinical situation. The volume of dialysis fluid infused into the peritoneal cavity is adjusted to the body size. In children, the peritoneal surface area is related more to body surface area than to weight and the infused volume is typically 800–1,100 mL/m^2, starting with lower volumes. The exchange time is 1 hour (inflow 10 minutes, dwell 30 minutes, outflow 20 minutes). In children with fluid overload and hyperkalemia, the dialysate fluid used may be hypertonic (2.5–3%) and with shorter cycles. The duration of dialysis depends on the patient's requirement.

Complications

Leakage, poor drainage and ultrafiltration are commonly encountered. Peritonitis is a constant threat, especially if the catheter has been manipulated. Peritonitis during acute peritoneal dialysis is managed with intraperitoneal or intravenous antibiotics; catheter removal is required if a stiff catheter was used or response to therapy is inadequate at 48–72 hours.

Contraindications

Contraindications to dialysis include recent abdominal surgery, necrotizing enterocolitis and presence of a ventriculoperitoneal shunt, because of the risk of peritonitis.

Hemodialysis

Hemodialysis is the most efficient method of RRT, accomplishing solute transfer and ultrafiltration at high rates. It is effective in acute

settings in management of volume overload, intoxication, tumor lysis syndrome or hyperammonemia. It is not suited for patients with hemodynamic instability or bleeding tendency and in small infants where vascular access is difficult to establish.

Vascular Access

Acute vascular access for hemodialysis is most often accomplished by placing a double lumen catheter in the internal jugular or femoral vein. These sites provide adequate blood flow and are acceptable for short-term use in the hospitalized patient. Due to the risk of soiling, femoral access should only be used in emergency situations.

Dialyzers

The size of the dialyzer depends upon body size, with the dialyzer area approximating the patient surface area. Newer generation dialysis membranes constructed from materials such as polysulfone and polymethylmethacrylate cause less proinflammatory cytokine activation.

Prescription

The prescription takes into account the extracorporeal blood volume in dialyzer and tubings, rates of blood and countercurrent dialysate flow and the desired duration and ultrafiltration. Heparin is the preferred anticoagulant; saline flushes are used to prevent clots in the circuit if heparin is contraindicated by bleeding diathesis. Based on relative ratio of body size and volume in tubings, the circuit may require priming with blood, saline or 5% albumin. The ultrafiltration achieved through dialysis depends on the hemodynamic status of the child.

Complications

Hypotension, leg cramps, abdominal pain and vomiting may result from excessive ultrafiltration or dyselectrolytemia. Problems related to vascular access, such as thrombosis, stenosis, and infection, may require catheter removal.

Continuous Renal Replacement Therapy

Continuous renal replacement therapy (RRT) is defined as any extracorporeal blood purification therapy intended to substitute for acutely impaired renal function over an extended period of time and prescribed continuously for more than 24 hours. CRRT is classically used to refer to continuous venovenous hemofiltration, continuous venovenous hemofiltration with dialysis or a combination of convective and diffusive clearance, as in continuous venovenous hemodiafiltration. CRRT is the preferred modality in sick patients in pediatric intensive care units. It mimics the functioning in a normal kidney where solute and fluid are continuously removed. CRRT is more precise in solute and fluid removal than peritoneal dialysis, and is tolerated by sick children with hypotension requiring multiple inotropes.

Issues related to vascular access in CRRT are the same as for hemodialysis. Heparin has been used as bolus or infusions; regional anticoagulation using citrate or no anticoagulation (saline flushes) may also be used. A replacement solution, typically bicarbonate based, is required. Blood and dialysate flow rates are considerably lower as compared to hemodialysis. The ultrafiltration targets are titrated to the fluid balance and hemodynamic status and choice between convective and diffuse modality is based on physician preference. While convective clearance theoretically achieves removal of cytokines and toxins, any modality may be used for small molecule clearance. CRRT requires to be carried out in an intensive care unit for close supervision. The chief disadvantages are its cost, the need for technical expertise and equipment, and risk of hemorrhage in critically sick children.

OUTCOMES

Currently there are no randomized trials comparing clinical outcomes of the various dialysis modalities in children. Results of a study in adult patients failed to show benefit in survival from early versus late initiation of RRT. Timely initiation of RRT for AKI in children with fluid overload and sepsis is considered useful in enabling recovery. Retrospective studies suggest that patient survival is predicted by underlying diagnosis and hemodynamic stability, and the severity of illness is more closely associated with risk of mortality than the choice of RRT.

IN A NUTSHELL

1. Early provision of RRT in AKI may prevent life-threatening complications of uremia, fluid overload and dyselectrolytemia.
2. The available modalities for RRT include hemodialysis and peritoneal dialysis.
3. Hemodialysis is intermittent therapy, even when prolonged beyond the standard 4 hours prescription.
4. Continuous RRT is defined as any extracorporeal blood purification therapy intended to substitute for acutely impaired renal function over an extended period of time and prescribed continuously for more than 24 hours.
5. Timely initiation of RRT for AKI in children with fluid overload and sepsis is considered useful in enabling recovery.

Chapter 41.13
Hemolytic Uremic Syndrome
Aditi Sinha, Arvind Bagga

Hemolytic uremic syndrome (HUS) is a heterogeneous group of disorders characterized by the triad of microangiopathic hemolytic anemia, thrombocytopenia and acute renal insufficiency. Histologically, thrombi occlude blood vessels in the micro-vasculature, termed thrombotic microangiopathy (TMA). While the disease is uncommon (incidence 0.7–8 cases/100,000 population/year), it is an important cause of acute kidney injury (AKI) in children and the most common cause of childhood AKI requiring dialysis.

ETIOLOGY

Conditions that result in HUS are listed in **Table 1**. Broadly, two forms are recognized. *Shiga toxin-associated HUS* is more common, occurs in young children and is associated with shiga toxin-producing enteropathogens, typically *Escherichia coli* O157:H7 or *Shigella dysenteriae*. *Atypical HUS* (aHUS) refers to HUS not caused by shiga toxin, and comprises diverse conditions including abnormalities in regulation of the complement cascade, cobalamin pathway and deficiency of von Willebrand protease, a metalloproteinase with thrombospondin motifs 13 (ADAMTS13). HUS may follow precipitating events like infections, drugs, transplantation, pregnancy and autoimmune conditions, termed *secondary aHUS*.

Shiga Toxin-associated Hemolytic Uremic Syndrome (STEC-HUS)

Diarrhea or dysentery due to shiga toxin-producing *E. coli* (STEC) (chiefly O157:H7; O104:H4 in a recent epidemic in west Europe)

Table 1 Classification of hemolytic uremic syndrome and related disorders

Infection induced
• *Shiga and verotoxin-producing bacteria:* Enterohemorrhagic *E. coli*; *S. dysenteriae* type 1
• Invasive infection with *Streptococcus pneumoniae*
• *Other bacterial infections: Citrobacter*, *Salmonella*, *Campylobacter*, *Bartonella*
• *Viruses:* Coxsackievirus, echovirus, influenza, varicella, HIV, Epstein-Barr virus
Disorders of complement regulation
• Inherited disorders of complement regulation
• Acquired disorders of complement regulation; antibodies to complement factor H
von Willebrand protease (ADAMTS13) deficiency
• Inherited deficiency of ADAMTS13 (Upshaw-Schulman syndrome)
• *Acquired ADAMTS13 deficiency:* Autoimmune; drug-induced
Defective cobalamin metabolism
Drug induced
Quinine, mitomycin, ticlopidine, clopidogrel, calcineurin inhibitors, oral contraceptives
Other causes

ADAMTS13 a metalloproteinase with thrombospondin motifs 13.

or *Shigella dysenteriae 1* (in Asia and Africa) is followed by HUS in about 10–15% cases. The incidence is highest in children below 5-year-old, at 6 per 100,000 per year. Shiga toxin-mediated injury chiefly targets endothelia with globotriaosylceramide 3 (Gb3) receptors, found in kidneys, brain, liver, pancreas and heart. The risk of HUS is high for certain strains (e.g., O104:H4) and infection with shiga toxin 2 (rather than shiga toxin 1) producing organisms, and use of quinolones within 3 days of infection. Interference with protein synthesis incites cytokine production and increased expression of adhesion molecules on endothelial cells, triggering coagulation and fibrin deposition in the microvasculature, with sequestration of red cells and platelets. TMA in STEC-HUS predominantly affects glomeruli.

Atypical HUS

Atypical HUS is uncommon (prevalence 2–7 per million children), and has a chronic and relapsing course and risk of end stage renal disease (ESRD). While distinguished from classic HUS by absence of diarrheal prodrome, the disease is often triggered by febrile, respiratory and even diarrheal infections. Microangiopathy affects interlobular arteries and result in severe hypertension and progressive renal insufficiency. Predisposing factors include abnormalities in complement regulation, infection with pneumococci, cobalamin deficiency, lupus and medications (cyclosporin, mitomycin) **(Table 1)**.

CLINICAL FEATURES

Shiga Toxin-associated HUS (STEC-HUS)

Within a week of profuse and usually bloody diarrhea (hemorrhagic colitis), patients develop fatigue, pallor and oligoanuria, with or without fluid overload, hypertension and edema. Most patients have mild disease managed with fluid restriction, nutrition support and control of hypertension. However, severe cases with anuria often require dialysis, and may show signs of extrarenal involvement, chiefly brain and pancreas, and uncommonly liver or heart. Cerebral involvement, manifest as irritability, altered consciousness and seizures, is noted in 3–50% cases.

Atypical Hemolytic Uremic Syndrome

The onset may be insidious or present with a rapidly progressive illness. Important clinical characteristics of patients with various forms of aHUS are summarized in **Table 2**. Based on age, the following etiologies are suspected: (1) less than 6-month-old: hereditary ADAMTS13 deficiency, methylmalonic aciduria; (2) infants and young children: STEC-HUS, *S. pneumonia*-associated HUS, complement factor H deficiency, mutations in diacylglycerol kinase ε (DGKE*)*; (3) school age children and adolescents: anticomplement factor H (anti-CFH) antibody-mediated HUS, CD46 deficiency, autoantibodies against ADAMTS13.

DIAGNOSIS

The diagnosis of HUS is based on documentation of azotemia, thrombocytopenia (platelets < 150,000/mm^3) and hemolysis, occurring with or without history of preceding diarrhea or dysentery. Hemolysis is identified as anemia, microangiopathy (fragmented RBC) on peripheral smear, reticulocytosis and increased lactate dehydrogenase; neutrophilic leukocytosis is seen in patients with shigellosis. Blood levels of urea and creatinine reflect the severity of renal failure. Urine sediment may be normal

Table 2 Common causes of atypical hemolytic uremic syndrome (aHUS)

Abnormal or deficient factor	Function	% of aHUS*	Minimum age	Low C3, %	ESRD^, %	Relapses, %	Post-transplant recurrence, %
C3	Central role in the complement cascade; substrate for C3 convertase; active form C3b is required for enzymatic complexes	2–10	> 1-year	70–80	60	50	40–70
Complement factor H	Binds C3b as cofactor for CFI-mediated cleavage to inactive iC3b; has decay accelerating activity for C3 convertase	20–30	< 1-month	30–50	50–70	50	75–90
Complement factor I	Serine protease; requires a cofactor to cleave C3b or C4b	4–10	< 1-month	20–30	50	10–30	60–80
Membrane cofactor protein or CD46	Binds C3b and C4b and has cofactor activity for both ligands	5–15	> 12-months	0–27	0–10	70–90	< 20
Complement factor B	Provides catalytic site for the C3 convertase	1–4	< 12-months	100	50	3/3	100
Anti-CFH antibody	Binds to factor H to reduce its cell surface complement regulatory activity	6–25	5–15 years	40–60	30–40	20–50	Low
Thrombomodulin	Accelerates CFI-mediated inactivation of C3b in presence of cofactors; helps inactivate C3a and C5a	3–5	1-month	50	50	30	NA
Diacylglycerol kinase ε	Not linked directly to the complement cascade; hypothetically causes a prothrombotic state	25–30% of < 1-year	< 12-months	Low C3 in 1 report	80–100	Yes; NA	NA

*No abnormality detected in ~40% cases.
^Or death within 1 year from onset.
Abbreviations: ESRD, end stage renal disease; NA, not available; CFI, complement factor I.

or show red cells and non-nephrotic range proteinuria. Coombs' test is positive in *S. pneumoniae*-associated HUS.

Table 3 lists important investigations in patients of HUS, including those to identify the underlying etiology. The diagnosis of STEC-HUS should be considered in patients older than 6 months with history of diarrhea or dysentery in the preceding 2 weeks. Establishing etiology requires either stool culture or polymerase chain reaction for shiga toxin; in those presenting late, serological response to bacterial lipopolysaccharide may be determined. Diagnosis of defect in cobalamin metabolism requires levels of plasma and urine homocysteine and methylmalonic acid.

Several patients with atypical HUS show low levels of complement C3 suggesting complement dysregulation; these patients require detailed analysis of components and regulators of the complement pathway. However, normal C3 does not exclude a complement disorder and 30–50% patients with complement dysregulation have normal C3 levels. Samples for complement studies should be taken before plasmapheresis or infusing blood products **(Flow chart 1)**. Facilities for complement studies are available in research laboratories, including at the All India Institute of Medical Sciences, New Delhi (details at *www.ispn-online.org*).

Histology

Histological features include intimal hyperplasia with thickening of arterioles and capillaries, endothelial swelling and detachment, subendothelial widening due to accumulation of cell debris, thrombi in vessel lumina and mesangiolysis **(Figs 1A and B)**. Patchy or extensive renal cortical necrosis may be seen. The lesions progress to glomerular sclerosis, interstitial fibrosis and tubular atrophy. Similar changes may be present in the brain, heart, lungs, pancreas and the gastrointestinal tract.

MANAGEMENT

General management focuses on supportive care. This includes attention to fluid and electrolyte balance, management of hypertension, monitoring for extrarenal involvement, nutritional support and provision of renal replacement therapy as required. Most children develop some renal insufficiency and approximately two-thirds require dialytic support. Patients with severe anemia may need packed red cells. Platelet transfusions are limited to children with active bleeding since they might increase risk of microthrombi.

STEC-Hemolytic Uremic Syndrome

There is no specific treatment for STEC-HUS, with current management focusing on best supportive therapy and avoiding antidiarrheal drugs. While used anecdotally in patients with severe neurological symptoms or refractory hemolysis, current evidence does not support the use of antibiotics, plasma exchange, immunoadsorption, shiga toxin-binding agents and complement inhibition (eculizumab) to ameliorate the disease course.

Atypical Hemolytic Uremic Syndrome

While there are no evidence-based guidelines on therapy, there is consensus on the need for prompt plasmapheresis or plasma exchanges, which forms the standard of care for patients with atypical or recurrent HUS. Patients with antifactor H antibodies benefit from additional use of immunosuppression to reduce

Table 3 Evaluation in patients with hemolytic uremic syndrome

- *Renal function tests*
- Complete blood counts with peripheral smear; schistocytes; reticulocyte count
- Direct Coombs test
- Lactate dehydrogenase, haptoglobin
- Complement C3
- *Urinalysis:* Proteinuria; hematuria

Based on suspected etiology

Shiga toxin-mediated HUS
- Stool or rectal swab culture
- Polymerase chain reaction for shiga toxin in stool
- Serum antibodies to lipopolysaccharide

Atypical HUS
- Complement factors H, I (ELISA)
- Membrane cofactor protein or CD46 (Flow cytometry)
- Antifactor H antibodies (ELISA)
- Sequencing for complement factors H, I, B, C3, CD46 and DGKE
- MLPA for CFHR1-5; CFH (copy number variation)

Streptococcus pneumoniae associated
Direct Coombs' test, blood culture, positive T-antigen (peanut agglutination)

Defective cobalamin metabolism
- Serum homocysteine, methionine (high performance liquid chromatography)
- Urine methylmalonic acid (tandem mass spectrometry)
- Urine and plasma organic acid chromatography
- Sequencing for *MMACHC* (gene for methylmalonic aciduria and homocystinuria type C)

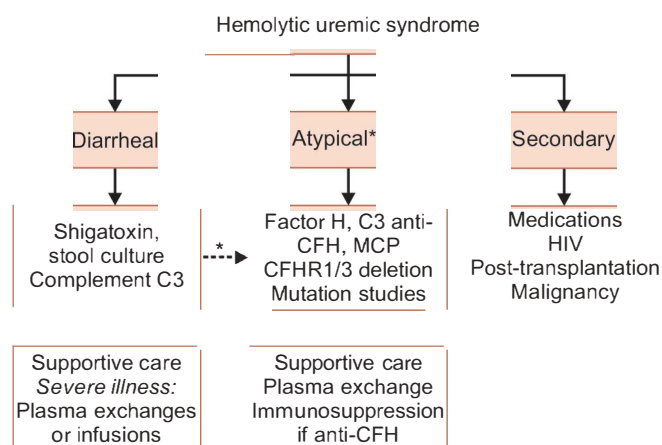
Thrombotic thrombocytopenic purpura
ADAMTS13 activity, ADAMTS13 antigen, anti-ADAMTS13 antibodies

Secondary HUS
- Antinuclear antibodies; antiphospholipid antibodies, antineutrophil cytoplasmic antibodies
- Antibodies to human immunodeficiency virus
- Polymerase chain reaction for cytomegalovirus, Epstein-Barr virus

Abbreviations: ADAMTS13, a disintegrin and metalloproteinase with a thrombospondin type 1 motif, member 13; CFHR, complement factor H related; DGKE, diacylglycerol kinase ε; MLPA, multiplex ligation-based probe amplification; ELISA, enzyme-linked immunosorbent assay; CFH, complement factor H.

Flow chart 1 Proposed algorithm for evaluation of patients with hemolytic uremic syndrome

Hemolytic uremic syndrome

Diarrheal	Atypical*	Secondary
Shigatoxin, stool culture Complement C3	Factor H, C3 anti-CFH, MCP CFHR1/3 deletion Mutation studies	Medications HIV Post-transplantation Malignancy
Supportive care *Severe illness:* Plasma exchanges or infusions	Supportive care Plasma exchange Immunosuppression if anti-CFH	


*Consider atypical HUS, if less than 6 months; nondiarrheal trigger, low C3, relapses or family history.
Abbreviations: MCP, membrane cofactor protein; CFH, complement factor H; CFHR, CFH related.
Figures 1A and B Features of thrombotic microangiopathy showing (A) Severe mesangiolysis; (B) Glomerulus with endothelial swelling and capillary lumina occluded with fibrin thrombi

antibody production. The use of eculizumab, a high affinity monoclonal antibody targeted against C5, is reported to benefit patients with HUS associated with activation of the complement cascade.

Plasmapheresis (Plasma Exchange)

Plasma exchanges are expected to replace absent or mutated complement regulators and/or remove circulating anti-CFH antibodies. Plasma exchanges should begin as soon as possible, preferably within 24 hours of the diagnosis of aHUS, without awaiting biopsy diagnosis or results of complement studies. Most centers perform 1.5 volume exchanges daily for 5 days or until hematological remission (platelets > 150,000/mm^3; no hemolysis), followed by 4–6 plasma exchanges each on alternate days, twice weekly and eekly.

Eculizumab

This high affinity monoclonal antibody against C5 blocks terminal complement activation. This agent is emerging as the standard of car for patients with atypical HUS. Eculizumab is preferred in patients with unsatisfactory response to 3–5 days' plasmapheresis and inability to perform plasmapheresis, due to difficult vascular access or other complications. The medication is expensive, and not available in India.

Monitoring

Patients should be monitored for hematological remission and for renal dysfunction, proteinuria and hypertension at follow-up. Patients with atypical HUS should be screened for relapses, particularly following infections. Outcome of STEC-HUS is satisfactory, with resolution of renal impairment over a few weeks. Twenty to thirty percent cases have residual renal defects, ranging from proteinuria and hypertension to ESRD. Oligoanuria persisting for more than 4 weeks, cerebral involvement and cortical necrosis are associated with adverse prognosis. The long-term prognosis for patients with atypical HUS is guarded, with acute mortality of 25% and progression to ESRD in 50%. An unsatisfactory outcome is predicted in those with mutations in genes encoding CFH or CFI. Those with anti-CFH antibodies respond to plasma exchange and immunosuppression. Patients with abnormalities in CD46 are less likely to respond to plasma exchange and show relapses.

Renal transplantation is associated with 50% rate of recurrence in the allograft. The risk is high in patients with mutations in CFH or CFI, with 80% patients losing their graft, in contrast to mutations in CD46 where post-transplant recurrence is rare. Combined liver kidney transplantation or the use of eculizumab is recommended in the former. Patients with autoantibody-associated HUS requiring transplantation may need plasma exchanges and immunosuppressive therapy before and during transplantation.

Verhave JC, Wetzels JF, van de Kar NC. Novel aspects of atypical haemolytic uraemic syndrome and the role of eculizumab. Nephrol Dial Transplant. 2014;29:131-41.

IN A NUTSHELL

1. While HUS is a rare disease, it is an important cause of AKI in children and the most common cause of childhood AKI requiring dialysis.
2. Infection with shiga toxin-producing *E. coli* or *S. dysenteriae* is the chief cause of HUS; therapy is chiefly supportive and outcomes are satisfactory.
3. Abnormalities in complement regulation, secondary to mutations or presence of inhibitory autoantibodies, constitute an important cause of atypical HUS.
4. Apart from supportive therapy, specific treatment for patients with atypical HUS comprises of eculizumab and/or the use of plasma exchanges; immunosuppression is offered to patients with autoantibodies to complement factor H.

Chapter 41.14
Renal Tubular Acidosis
Arvind Bagga, Aditi Sinha

Renal tubular acidoses (RTAs) are transport defects secondary to reduced proximal tubular reabsorption of bicarbonate (HCO_3^-), distal secretion of protons (hydrogen ion, H^+) or both, resulting in impaired capacity for net acid excretion and persistent hyperchloremic metabolic acidosis, in the absence of significant decrease in glomerular filtration rate (GFR).

PATHOPHYSIOLOGY AND ETIOLOGY

The proximal renal tubule is the chief site of solute and water reabsorption in the nephron. Approximately 60% of the filtered sodium (Na^+) is reabsorbed in the proximal segments, along with water, potassium (K^+), HCO_3^-, phosphate, amino acids and low molecular weight proteins. In contrast, the distal tubule has an important role in the final urine concentration and pH. Specialized transporters are involved in the regulation of Na^+ and K^+ reabsorption and H^+ secretion. Figures 4 and 5 (in Chapter 41.1) illustrate the mechanisms for HCO_3^- absorption in the proximal tubule, and H^+ secretion by the distal tubule. While intercalated cells of the cortical collecting duct are involved in H^+/HCO_3^- transport, principal cells mediate Na^+/K^+ exchange under influence of mineralocorticoids. Na^+ transport by principal cells creates a lumen-negative transepithelial potential that promotes H^+ secretion by intercalated cells. Based on mechanisms and site of dysfunction, RTAs are classified as proximal (type 2) RTA, distal (type 1) RTA and type 4 RTA.

Proximal Renal Tubular Acidosis

The primary defect is bicarbonaturia due to reduced renal threshold for HCO_3^- excretion. Proposed mechanisms include deficient carbonic anhydrase on the brush border, and defective pump secretion or function of the Na^+/HCO_3^- cotransporter, H^+ ATPase, Na^+/H^+ antiporter and the Na^+/K^+ ATPase. However, proximal RTA rarely represents an isolated defect and is more commonly a part of generalized proximal tubular dysfunction, termed Fanconi syndrome, characterized by tubular proteinuria and aminoaciduria and variable degrees of bicarbonaturia, phosphaturia, electrolyte wasting and glucosuria. **Box 1** lists conditions associated with proximal RTA, including known genetic defects and secondary conditions.

Distal Renal Tubular Acidosis

This is characterized by metabolic acidosis secondary to decreased secretion of H^+ ions, resulting in lower values for titratable acidity and NH_4^+ secretion than required to keep pace with daily acid production. In hypokalemic distal RTA (classic RTA or type 1 RTA), urine pH cannot reach maximal acidity (i.e., remains > 5.3) despite systemic acidemia indicating low H^+ concentration in the collecting duct. The condition is secondary to either a secretory (rate) defect or a gradient (permeability) defect. In the former, the rate of secretion of H^+ is low for the degree of acidosis, e.g., secondary to defective function of H^+ ATPase, H^+/K^+ ATPase, or the Cl^-/HCO_3^- exchanger. The gradient (permeability) defect is characterized by an appropriate rate of H^+ secretion but an increased backleak, resulting in dissipation of the pH gradient. Hypokalemia, a common finding in patients with distal RTA, is attributed to increased tubular losses of K^+ that are enhanced by aldosterone stimulation following urinary Na^+ losses and volume

---

BOX 1   Etiology of proximal renal tubular acidosis (RTA)

Inherited defects (mutated gene; encoded protein)
- Isolated proximal RTA
  – Autosomal recessive type (*SCL4A4*; sodium bicarbonate cotransporter 1)[*]
  – Autosomal dominant type (unknown)
- Multiple tubular dysfunction (Fanconi syndrome)
  – Isolated Fanconi syndrome, autosomal dominant type (unknown)
  – Isolated Fanconi syndrome, autosomal recessive type (unknown)
  – Dent's disease (*CLCN5*; renal chloride channel)
  – Cystinosis (*CNS*; cystinosin)
  – Tyrosinemia type 1(*FAH*; fumarylacetoacetate hydrolase)
  – Fanconi-Bickel syndrome (*GLUT2/SLC2A2*; glucose transporter GLUT2)
  – Wilson's disease (*ATP7B*; copper-transporting polypeptide ATPase)
  – Galactosemia (*GALT*; galactose-1-phosphate uridylyltransferase)
  – Hereditary fructose intolerance (*ALDOB*; fructose-1-phosphate aldolase)
  – Lowe syndrome (*OCRL1*; phosphatidylinositol-4,5-bisphosphate-5-phosphatase)
  – Glycogen storage disease type 1 (*G6Pa*; glucose-6-phosphatase-alpha)
  – Multiple phenotypes (mitochondrial genes; various mitochondrial enzymes)
- Combined defect in proximal and distal acidification (type III RTA)
  – Associated with osteopetrosis and deafness (*CA2*; carbonic anhydrase type II)

Acquired defects
- Isolated proximal RTA
  – Carbonic anhydrase inhibitors (acetazolamide)
- Multiple tubular dysfunction (Fanconi syndrome)
  – Primary hyperparathyroidism
  – Sjögren syndrome
  – Vitamin D-dependent rickets
  – Paroxysmal nocturnal hemoglobinuria
  – Acute tubulointerstitial nephritis with uveitis syndrome
  – Drugs: ifosfamide, valproate, aminoglycosides, cisplatin
  – Heavy metals and toxins: lead, cadmium, mercury, toluene (glue sniffing)

[*]*Associated with ocular and dental enamel defects, impaired intelligence and basal ganglia calcification.*

---

contraction. Hypercalciuria and hyperphosphaturia occur due to the release of calcium phosphate from bone in order to buffer excess H^+ during acidosis, and the direct effects of acidosis on tubular reabsorption of these ions. Hypocitraturia results from citrate utilization in proximal tubular cells, and due to the high luminal pH favoring conversion of citrate^{3-} to the readily reabsorbable citrate$^-$. *Incomplete distal RTA* refers to milder variants of classic distal RTA in which defective tubular H^+ secretion does not lead to systemic acidosis, since daily acid excretion is enabled by enhanced ammoniagenesis. Important etiologies of distal RTA are listed in **Box 2**.

Distal RTA with hyperkalemia may occur due either to (1) voltage defect caused by insufficient negative intratubular potential at the level of cortical collecting duct (hyperkalemic distal RTA); or (2) rate defect due to aldosterone deficiency or resistance (type 4 RTA). The voltage defect leads to reduced secretion of H^+ and K^+, decreased trapping and excretion of NH_4^+ and hyper- or normokalemia. Apart from the latter finding, the voltage defect resembles classic distal RTA.

Type 4 Renal Tubular Acidosis

Characterized by hyperkalemic acidosis and intact ability to lower urine pH, the condition is caused by aldosterone resistance or deficiency **(Box 3)**. Aldosterone increases Na^+ absorption, resulting in a negative intratubular potential, increases urinary K^+

Inherited defects (mutated gene; encoded protein)

- Isolated distal RTA
  - Autosomal dominant type (*SCL4A1*; anion exchanger 1, AE1)
  - With hemolytic anemia; autosomal recessive (*SCL4A1*; AE1)
  - With early hearing loss; autosomal recessive (*ATP6V1B1*; B1 subunit of H^+ ATPase)
  - With normal hearing or delayed hearing loss; autosomal recessive (*ATP6V0A4*; A4 subunit of H^+ ATPase)
- Combined defect in proximal and distal acidification (type III RTA)
  - Associated with osteopetrosis and deafness (*CA2*; carbonic anhydrase type II)

Acquired defects

- Systemic lupus erythematosus
- Sjögren syndrome
- Sickle cell anemia
- Obstructive uropathy
- Reflux nephropathy
- Nephrocalcinosis
- Amphotericin B toxicity.

BOX 3 Etiology of type 4 (hyperkalemic) renal tubular acidosis

Inherited defects (mutated gene; encoded protein)

- Congenital adrenal hyperplasia; autosomal recessive (*CYP21*; 21 hydroxylase aldosterone synthase or P450c21; *CYP11B2*; aldosterone synthase)
- Pseudohypoaldosteronism (PHA); autosomal dominant (*NR3C2*; mineralocorticoid receptor)
- PHA; autosomal recessive (*SCNN1B*; epithelial sodium channel)
- PHA type 2 or Gordon syndrome; autosomal recessive (*PHA2B, PHA2C*; WNK1, WNK4)

Acquired defects

- Aldosterone deficiency without renal disease
  - Addison disease
  - Isolated aldosterone deficiency
  - Adrenal tuberculosis; necrosis
- Aldosterone deficiency in chronic renal insufficiency
  - Obstructive uropathy
  - Interstitial nephritis
  - Nephrocalcinosis
- Aldosterone resistance
  - Post-transplantation
  - *Drugs:* Amiloride, spironolactone, angiotensin-converting enzyme (ACE) inhibitors, heparin, nonsteroidal anti-inflammatory drugs (NSAIDs), calcineurin inhibitors.

losses by enhancing membrane permeability to K^+ and stimulating the basolateral $Na^+/K^+/ATPase$, and directly stimulates the proton pump [Fig. 5 (in Chapter 41.1)]. Aldosterone deficiency or resistance causes hyperkalemic metabolic acidosis. The net H^+ excretion is decreased due to inhibition of ammoniagenesis by hyperkalemia. Although maximally acidic urine (pH < 5.3) can be formed, indicating the ability to establish a maximal H^+ gradient, ammonium excretion is low resulting in positive anion gap.

CLINICAL FEATURES

The most common symptom of tubular dysfunction is poor growth. Additional features that suggest RTA include polyuria, polydipsia, preference for savory foods, refractory rickets and recurrent episodes of dehydration, fever and constipation. Polyuria is caused by osmotic diuresis due to presence of excessive solutes in the tubules and impaired urinary concentration due to persistent hypokalemia.

Proximal Renal Tubular Acidosis

These children present with stunted growth, and/or irritability, anorexia and listlessness. Rickets is unusual in isolated proximal RTA but is common in Fanconi syndrome due to the associated hypophosphatemia. While symptoms related to hypokalemia (e.g., weakness, paralysis) are uncommon, hypokalemia and consequent polyuria are often present in Fanconi syndrome. Nephrocalcinosis and urolithiasis are not seen except with Dent's disease and Lowe syndrome. All children with proximal RTA require evaluation for Fanconi syndrome, including secondary forms **(Box 1)**.

Distal Renal Tubular Acidosis

Features include failure to thrive, polyuria, refractory rickets, and symptoms of hypokalemia, including muscle weakness, neck flop and even paralysis. Hypercalciuria, hypocitraturia and high urine pH contribute to occurrence of calcium phosphate stones. Incomplete forms of distal RTA are suspected in patients presenting with nephrocalcinosis or nephrolithiasis without systemic acidosis; diagnosis is made on demonstrating hypercalciuria and inability to lower urinary pH when acidosis is induced pharmacologically. In children, distal RTA is almost always primary; few have early or delayed sensorineural deafness or ovalocytosis and hemolytic anemia. Presentation in later childhood should prompt evaluation for systemic lupus or Sjögren syndrome.

Type 4 Renal Tubular Acidosis

Findings of the underlying disease (hypoaldosteronism or resistance to action of aldosterone) predominate over features of tubular acidosis. There is nephrocalcinosis or urolithiasis and bone disease is rare. Advanced tubulointerstitial diseases leading to mineralocorticoid resistance should be suspected, particularly in older children. Aldosterone unresponsiveness, associated with obstructive uropathy, is more common than aldosterone deficiency. Patients with pseudohypoaldosteronism (PHA) type 1 present with salt wasting, hyperkalemia and metabolic acidosis with high levels of plasma renin and aldosterone. Patients with PHA type 2 show hypertension, metabolic acidosis, hyperkalemia and suppressed plasma renin activity.

DIFFERENTIAL DIAGNOSIS

Metabolic acidosis may result from extrarenal processes, which result in either increased endogenous acid synthesis (e.g., ketoacidosis) or enhanced HCO_3^- losses. Intestinal and pancreatic secretions and bile have high quantities of HCO_3^-, therefore conditions like diarrhea, removal of pancreatic or intestinal secretions or bile by tube drainage or fistula leads to loss of HCO_3^- and metabolic acidosis. Hyperchloremic acidosis may also result from ureterosigmoidostomy due to presence in the colon of an anion exchange pump that absorbs luminal Cl^- (of urinary origin) and exchanges it for HCO_3^-, and due to colonic absorption of NH_4^+ (of urinary origin) that releases H^+ when metabolized in the liver. Cholestyramine also causes metabolic acidosis by acting as anion exchange resins, where colonic luminal HCO_3^- is absorbed in exchange for Cl^- released by the resin.

LABORATORY EVALUATION

Evaluation in patients with metabolic acidosis and suspected RTA requires consecutive tests as detailed below and in **Table 1**.

Plasma anion gap All types of RTA are associated with hyperchloremic normal anion gap metabolic acidosis. Hence, assessment of the anion gap helps distinction between RTA and diarrhea that causes hyperchloremic acidosis with normal anion

Table 1 Important tests in the evaluation of patients with metabolic acidosis

Evaluation	Calculation; normal level	Interpretation in metabolic acidosis
Plasma anion gap	$[Na^+] - \{[Cl^-] + [HCO_3^-]\}$ *Normal:* 8–16 mEq/L	*Increased:* Diabetic ketoacidosis; lactic acidosis; inborn errors; poisoning; uremia *Normal:* Renal tubular acidosis (RTA); diarrhea; impaired renal function
Urine anion gap	Urinary $[Na^+] + [K^+] - [Cl^-]$ *Normal:* Positive	*Positive:* Diarrhea; extrarenal losses of HCO_3^- *Negative:* RTA
Urine pH	$- \log_{10}[H^+]$ *Normal:* 4.6–8.0	*< 5.3:* Normal response; proximal RTA; type 4 RTA *> 5.3:* Distal RTA (classic, incomplete); hyperkalemic distal RTA
Fractional excretion of bicarbonate (%)	$\dfrac{\text{Urine } HCO_3^- \times \text{Plasma creatinine}}{\text{Plasma } HCO_3^- \times \text{Urine creatinine}} \times 100$ *Normal:* < 5%	*< 5%:* Normal, distal RTA, type 4 RTA *5–15%:* Distal RTA *> 15%:* Proximal RTA
Fractional excretion of phosphate (%)	$\dfrac{\text{Urine } PO_4^{3-} \times \text{Plasma creatinine}}{\text{Plasma } PO_4^{3-} \times \text{Urine creatinine}} \times 100$ *Normal:* < 5–15%	*< 5–12%:* Normal, distal RTA, type 4 RTA *> 15%:* Proximal RTA
Transtubular potassium gradient	$\dfrac{\text{Urine } K^+ \times \text{Plasma osmolality}}{\text{Plasma } K^+ \times \text{Urine osmolality}}$ *Normal:* 6–12	*In hyperkalemia:* > 10: normal response *< 8:* Type 4 RTA

gap, from diabetic ketoacidosis, lactic acidosis and other causes of increased anion gap acidosis **(Table 1)**. While advanced renal failure with GFR below 15 mL/min is associated with metabolic acidosis and elevated anion gap, normal anion gap acidosis is often noted in patients with estimated GFR 20–50 mL/min.

Urine anion gap (urine net charge) The difference between the sum of urinary Na^+ and K^+ and urinary Cl^- indirectly estimates NH_4^+ excretion in patients with hyperchloremic metabolic acidosis. Since the sum of charges on urinary cations and anions is equal, and the difference between urinary unmeasured anions (sulfates, phosphates, organic anions) and cations (calcium, magnesium) is fairly constant at about 80 mEq/L, hence:
$Na^+ + K^+ + NH_4^+ + \text{Unmeasured cations} = Cl^- + \text{Unmeasured anions}$;
or
$NH_4^+ = [\text{Unmeasured anions} - \text{Unmeasured cations}] -$
$$[Na^+ + K^+ - Cl^-];$$
or
$NH_4^+ = 80 - \text{Urinary anion gap}$; *or* Urinary anion gap $= 80 - NH_4^+$.

Under normal circumstances, the urinary anion gap is positive due to the presence of dissolved anions. Patients with systemic acidosis from extrarenal HCO_3^- losses (e.g., diarrhea) have intact mechanisms of renal acidification resulting in enhanced NH_4^+ synthesis and excretion along with Cl^- ions, causing the urinary anion gap to become negative. A positive urinary anion gap indicates inappropriately low renal NH_4^+ excretion, as in patients with all forms of RTA. The test enables distinction between patients with RTA, in whom urinary NH_4^+ excretion is low, from extrarenal HCO_3^- losses (e.g., diarrhea) where its excretion is high.

Urine pH Urine pH measures the concentration of free H^+ and assesses the integrity of distal H^+ secretion. In presence of systemic acidosis, urine pH is normally less than 5.3; pH greater than 5.3 suggests defective distal urinary acidification. Urine pH values are less than 5.3 in subjects with systemic acidosis due to type 4 RTA and those with proximal RTA when filtered load of HCO_3^- is low (plasma $HCO_3^- < 15$ mEq/L). The pH should be measured electrometrically on fresh voided specimen, since dipsticks are unreliable and urine left standing might get contaminated with urea splitting organisms, resulting in high urine pH.

Induced systemic acidosis If systemic acidosis is absent, an oral load of ammonium chloride is given, followed by the measurement of urine pH and NH_4^+ excretion. A decline in plasma CO_2 content by 3–5 mEq/L is accompanied by fall in urine pH to less than 5.3.

Bicarbonate loading test Sodium bicarbonate ($NaHCO_3$) is given orally or as an intravenous (IV) infusion, while measuring urine pH in timed samples collected under mineral oil. Loading is continued till consecutive samples show urine pH greater than 7.5 and plasma HCO_3^- greater than 22–24 mEq/mL. The fractional excretion of HCO_3^- ($FEHCO_3^-$) and urine to blood (U-B) PCO_2 gradient are measured to enable characterization of RTA.

Urine to blood CO_2 gradient Loading with $NaHCO_3$ makes luminal HCO_3^- available to combine with H^+ secreted by distal tubules. Carbonic acid dehydrates to form CO_2 that is trapped in the tubular lumen. In presence of urine pH greater than 7.5 and normal plasma HCO_3^-, the urine PCO_2 should exceed 70 mm Hg and the U-B PCO_2 gradient is greater than 20 mm Hg if the distal acidification is intact. Patients with decreased rates of tubular H^+ secretion (classical distal RTA) show urine PCO_2 less than 50 mm Hg and U-B PCO_2 less than 10 mm Hg. Patients with other forms of RTA show normal urinary PCO_2 values. The U-B PCO_2 gradient is considered a sensitive indicator of distal acidification.

Fractional excretion of bicarbonate Proximal tubules normally reabsorb almost all filtered HCO_3^-. Following alkalization to normalize serum HCO_3^- (> 22 mEq/L), $FEHCO_3^-$ provides a useful assessment of proximal tubular handling of HCO_3^-: while values greater than 15% indicate proximal RTA, levels are in the normal range (< 5%) in distal and type 4 RTA.

The interpretation of the above tests is summarized in **Tables 1 and 2**. Based on initial evaluation, the following additional tests may be useful.

Proximal Renal Tubular Acidosis

The diagnosis of proximal RTA requires evaluation of other proximal tubular functions. These include assessment of (1) phosphate excretion, (2) aminoaciduria, (3) glucosuria, (4) low molecular weight proteinuria (e.g., β_2-microglobulin), (5) hypercalciuria and (6) rickets. Patients should be screened for cystinosis, galactosemia and Wilson's disease.

Tests for phosphate handling Low levels of plasma phosphate and increased fractional excretion of phosphate indicate proximal tubular phosphate wasting, noted in Fanconi syndrome. The fractional excretion of phosphate is determined on a timed (6 hours, 12 hours or 24 hours) urine specimen and is normally less than 5–12%. The tubular reabsorption of phosphate (TRP, 100 – fractional excretion) is 88–95%. Since TRP varies according to

Table 2 Investigations to differentiate types of renal tubular acidosis (RTA)

	Proximal RTA	Distal RTA		Type 4 RTA
		Classic	Hyperkalemic	
Plasma K^+	Normal/low	Normal/low	High	High
Urine pH	< 5.3	> 5.3	> 5.3	< 5.3
Urine anion gap	Positive	Positive	Positive	Positive
Urine NH_4^+	Low	Low	Low	Low
Fractional HCO_3^- excretion	> 10–15%	< 5%	< 5%	> 5–10%
U-B PCO_2 mm Hg	> 20	< 20	$</>$ 20	> 20
Urine Ca^{2+}	Normal	High	High	Normal/low
Other tubular defects	Often present	Absent	Absent	Absent
Nephrocalcinosis	Absent	Present	Present	Absent
Bone disease	Common	Often present	Uncommon	Absent

Abbreviation: U-B PCO_2, urine to blood PCO_2 gradient

the plasma phosphate and GFR, tubular maximum for phosphate, corrected for GFR is a sensitive tool of phosphate reabsorption, the normal value being 2.8–4.4 mg/dL.

Distal Renal Tubular Acidosis

An ultrasonography is performed to detect nephrocalcinosis and/or calculi. Urinary excretion of calcium and citrate is measured to detect hypercalciuria and hypocitraturia. All patients should undergo hearing evaluation; evaluation for lupus, osteopetrosis, Sjögren syndrome and chronic hepatitis is done in patients presenting at an older age.

Fludrocortisone furosemide test Administration of furosemide (2 mg/kg, with or without fludrocortisone 0.02 mg/kg) unmasks the defect in patients with distal RTA by increasing distal Na^+ delivery and reabsorption, leading to luminal electronegativity in the cortical collecting tubule. In healthy individuals, this results in urine pH less than 5.3 and increase in K^+ excretion. In patients with hypokalemic distal RTA, the urine pH does not fall but the K^+ excretion increases, indicating intact function of principal cells. Patients with hyperkalemic distal RTA have a primary defect in cortical Na^+ reabsorption and do not show increase in H^+ or K^+ excretion since luminal electronegativity is not enhanced. Patients with type 4 RTA and proximal RTA show normal response.

Type 4 Renal Tubular Acidosis

Work-up includes evaluation for obstructive uropathy or tubulointerstitial disease. Measurement of plasma renin activity and aldosterone levels are useful. The transtubular potassium gradient (TTKG) is useful in diagnosing type 4 RTA and in conjunction with mineralocorticoid challenge helps distinguish deficiency from aldosterone resistance.

Transtubular potassium gradient This test is an index of K^+ gradient in the distal tubular lumen and interstitium and provides an accurate assessment of aldosterone effect on late distal and cortical collecting tubules in patients with hyperkalemia and normal renal function. Normal individuals have TTKG between 6 and 12; in presence of hyperkalemia, TTKG should rise to greater than 10 **(Table 2)**. Inappropriately low TTKG (< 8) suggests hypoaldosteronism or tubular resistance to aldosterone;

subsequent rise in TTKG to greater than 7 upon administering fludrocortisone suggests hypoaldosteronism.

TREATMENT

Proximal Renal Tubular Acidosis

Correction of acidosis may require administration of 5–20 mEq/kg/day of alkali, often as $NaHCO_3$ (5–8 mEq/kg/day). Since large amounts of alkali are lost in urine as HCO_3^-, restriction of dietary sodium and administration of hydrochlorothiazide (1.5–2 mg/kg/day) help by causing contraction of extracellular fluid volume that increases HCO_3^- reabsorption. Since thiazides enhance K^+ excretion, part of the alkali should be given as potassium citrate. Correction of acidosis results in improved growth velocity.

Patients with Fanconi syndrome require management of the underlying condition and replacement of losses of Na^+, K^+, HCO_3^- and phosphate. Adequate fluid intake is advised, particularly during infancy and illnesses. Rickets responds to supplements of phosphate (50–100 mg/kg/day), vitamin D and correction of acidosis.

Distal Renal Tubular Acidosis

Acidosis is corrected by administering alkali solution at 2–3 mEq/kg/day titrated to blood HCO_3^- levels. The requirement of HCO_3^- is high initially but decreases later. Hypokalemia should be treated before correcting the acidosis. While correction of acidosis decreases tendency for hypokalemia, patients may require prolonged potassium supplements. The response to therapy is significant but may be delayed, particularly in older children. While early treatment leads to reduction of hypercalciuria and increase in citrate excretion, use of thiazides may be required in persistent hypercalciuria.

Type 4 Renal Tubular Acidosis

Hyperkalemia requires potassium restriction regardless of etiology. Therapy is directed towards specific cause. Patients with aldosterone deficiency benefit from fludrocortisone supplementation. Therapy with thiazides corrects the abnormalities in PHA type 2. Patients with recessive form of PHA type 1 require large amounts of salt supplements.

SPECIFIC CONDITIONS ASSOCIATED WITH RENAL TUBULAR ACIDOSIS

Dent Disease

This rare X-linked disorder is characterized by low molecular weight proteinuria, hypercalciuria, nephrolithiasis and/or nephrocalcinosis and progressive renal failure. Most patients are detected when evaluated for renal calculi in adolescence. Findings may include features of proximal tubule dysfunction, such as aminoaciduria, glucosuria, hyperphosphaturia, kaliuresis and uricosuria, consistent with Fanconi syndrome; however, metabolic acidosis is uncommon. The underlying defect is a loss of function mutation in the gene encoding the voltage-gated chloride channel, *CLCN5*, or less commonly, that for phosphatidylinositol-4,5-bisphosphate-5-phosphatase, *OCRL1*.

Lowe Syndrome

The oculocerebrorenal syndrome of Lowe (OCRL) is a rare X-linked recessive condition characterized by anomalies of the eyes, nervous system and kidneys. Abnormalities include bilateral congenital cataract, strabismus, infantile onset glaucoma and keloids. Neurological involvement is manifest as hypotonia, hyporeflexia since birth, severe psychomotor retardation, behavioral abnormalities (temper tantrums, stereotypes, aggressiveness, obsessive compulsive behavior) and seizures. Fanconi syndrome is noted during early infancy. Facial dysmorphism includes frontal bossing, deep-set eyes, chubby cheeks and fair complexion.

The disease is caused by mutations in the gene *OCRL1* encoding the Golgi complex enzyme phosphatidylinositol-4,5-bisphosphate-5-phosphatase. Accumulation of the enzyme substrate, phosphatidylinositol bisphosphate alters protein trafficking, actin cytoskeleton polymerization and endocytosis. Mothers carrying the pathogenic mutation show punctate white-gray radial opacities in lens on slit lamp examination. Treatment is symptomatic, including cataract extraction, glaucoma control, physical and speech therapy, drugs to modify behavior and appropriate therapy for acidosis and bone disease. Most patients succumb to respiratory illness, seizures or renal failure by adulthood.

Cystinosis

This autosomal recessive condition is characterized by deposition of cystine crystals in the cornea, conjunctiva, bone marrow, leukocytes, lymph nodes and other organs. The disease is caused by mutations in the *CTNS* gene encoding for the protein, cystinosin that transports cystine from lysosomes to cytosol. Patients present in late infancy or early childhood with polyuria, polydipsia, failure to thrive and refractory rickets; photophobia is delayed but progressive. Renal injury, manifesting as Fanconi syndrome, progresses to end-stage renal disease by the end of first decade. Rarely, the disease is benign, with cystine deposits in cornea, bone marrow and leukocytes sparing the kidneys, or present as an intermediate form with incomplete Fanconi syndrome appearing during adolescence.

Diagnosis is suggested by detection of corneal cystine crystals on slit lamp examination; confirmation requires high levels of cystine in leukocytes. Management is for Fanconi syndrome and long-term administration of cysteamine that removes cystine from lysosomes. Cysteamine eyedrops, administered frequently, reduce corneal crystals. Long-term outcome is complicated by diabetes mellitus and hypothyroidism, in addition to end-stage renal disease.

Mitochondrial Cytopathies

Mitochondrial cytopathies are diverse disorders with abnormalities in the mitochondrial DNA causing dysfunction in various organs.

Impaired respiratory chain activity causes accumulation of reduced nicotinamide adenine dinucleotide (NADH), promoting conversion of acetoacetic acid into 3-hydroxybutyrate in mitochondria and pyruvate into lactate in cytosol. Patients present with neurological symptoms (apnea, lethargy, developmental delay, stroke like episodes, seizures, myoclonus, polyneuropathy, myopathy or hypotonia), but cardiac (cardiomyopathy, arrhythmias, heart block), endocrine and hematological (sideroblastic anemia, neutropenia, thrombocytopenia) involvement is common. Renal features include proximal tubular defects including Fanconi syndrome, tubulointerstitial nephritis, cystic renal disease and glomerulopathies. The tubulopathy is frequently associated with Pearson and Kearns-Sayre syndromes.

Diagnosis is suggested by presence of tubulopathy, proteinuria or hematuria along with neurological symptoms and high serum or cerebrospinal fluid lactate, with increased ratio of lactate to pyruvate. Investigations include magnetic resonance spectroscopy (elevated cerebral lactate), gas chromatography/mass spectrometry (elevated urinary organic acids) and genetic studies. Renal biopsy shows chronic tubulointerstitial changes with damaged proximal tubules; electron microscopy shows proliferation of abnormal mitochondria. Most inherited conditions are fatal. Apart from HCO_3^- and phosphate supplements, oral CoQ10 supplementation may be useful.

IN A NUTSHELL

1. Renal tubular acidosis is characterized either by failure of HCO_3^- reabsorption or lack of H^+ secretion by the distal tubule.
2. Clinical features include failure to thrive, muscle weakness, polyuria and rickets; nephrocalcinosis is common in distal RTA.
3. Key investigations that distinguish proximal from distal RTA include estimation of urine pH, $FEHCO_3^-$, and U-B PCO_2 gradient.
4. Additional investigations that assist in distinguishing proximal from distal RTA include estimation of urine calcium, screening for glucosuria, aminoaciduria and phosphate excretion, and ultrasonography for renal stones and nephrocalcinosis.
5. Principles of treatment include correction of acidosis and dyselectrolytemia.
6. Patients with Fanconi syndrome require additional supplements of phosphate and electrolytes; all patients should also be screened for an underlying cause.

Tubular Disorders
Kamran Afzal

HYPOKALEMIA AND METABOLIC ALKALOSIS

Hypokalemia, defined as serum potassium (K^+) concentration below 3.5 mEq/L, could result from dietary insufficiency, increased renal or extrarenal losses of potassium or its abnormal distribution. Most patients with metabolic alkalosis also have hypokalemia. Extrarenal and renal causes of hypokalemia with metabolic alkalosis are given in **Box 1**. In this section, renal tubular disorders that are associated with hypokalemia, metabolic alkalosis and normal blood pressure are discussed. These include chiefly Bartter syndrome and Gitelman syndrome, better described as *Bartter-like syndrome*. The presence of renal potassium loss and alkalosis with hypertension suggests conditions associated with mineralocorticoid excess.

Adult patients with Gitelman syndrome are more common than Bartter syndrome but during childhood the prevalence is similar. The disorders are uncommon in childhood but are possibly under diagnosed.

Bartter Syndrome

First reported by Bartter and colleagues in 1962, this group of inherited autosomal recessive renal tubular disorders is characterized by hypokalemia, metabolic alkalosis, hyper-reninemia and hyperaldosteronism with normal blood pressure, and increased urinary sodium, chloride, and potassium wasting. Based on age at presentation, the disease is categorized into neonatal Bartter and classic Bartter syndrome. Neonatal Bartter syndrome can be suspected before birth or can be diagnosed

BOX 1   Causes of hypokalemia with metabolic alkalosis

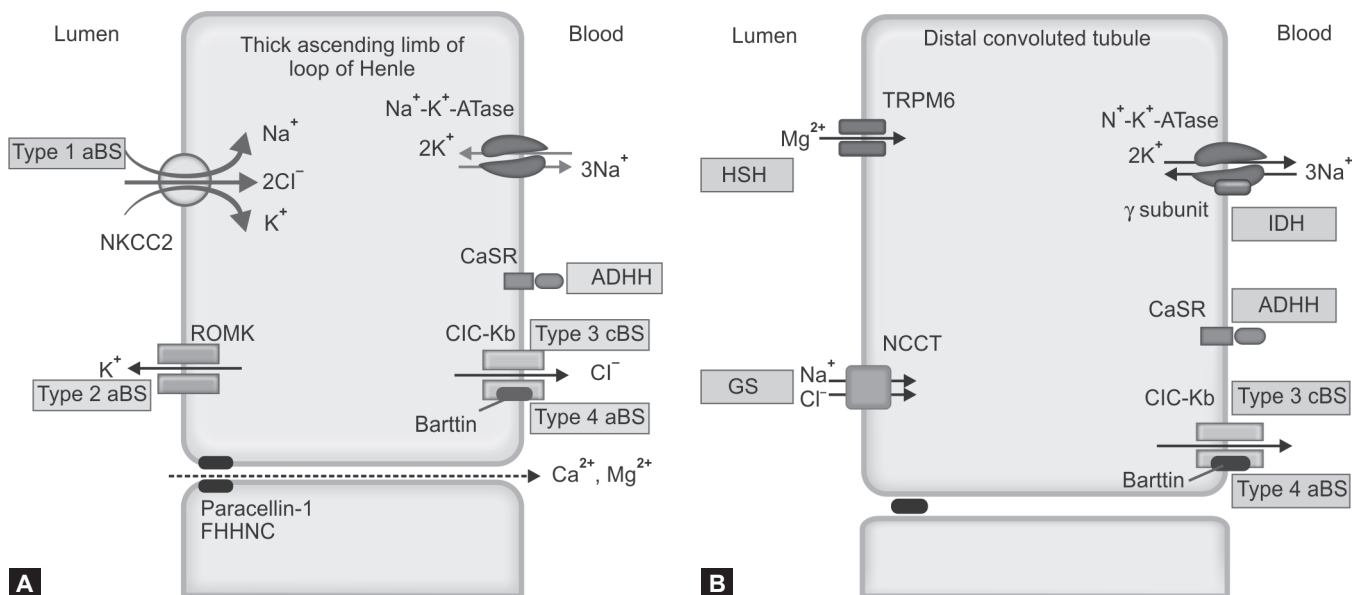
Extrarenal wasting of potassium
(urinary K^+ < 20 mEq/L) with metabolic alkalosis/normal pH
• Laxative abuse, villous adenoma, congenital chloride losing diarrhea, congenital pyloric stenosis
 	
Renal potassium wasting
(urinary K^+ > 20 mEq/L)
• With normal blood pressure
   – *Increased renin and aldosterone*: Bartter syndrome, Gitelman syndrome, magnesium losing tubulopathy, calcium losing tubulopathy, diuretic abuse
• With hypertension
   – *Decreased renin and aldosterone*: Pseudohyperaldosteronism (Liddle syndrome), syndrome of apparent mineralocorticoid excess
   – *Decreased renin and increased aldosterone (primary hyperaldosteronism)*: Aldosterone-producing adenoma, adrenocortical carcinoma
   – *Increased renin and increased aldosterone (secondary hyperaldosteronism)*: Renal artery stenosis, renin-secreting tumor.

immediately after birth. In the classic form, symptoms begin in neonates or in infants aged 2 years or younger.

Pathophysiology

There are four types of Bartter syndrome based on whether the underlying molecular defect involves the sodium-potassium-chloride cotransporter (NKCC2), ROMK potassium channel or the chloride channel, ClCK **(Figs 1A and B)**. Type 1, 2 and 4 are neonatal forms while type 3 is classic Bartter syndrome **(Table 1)**.

Clinical Features

Infants with neonatal Bartter syndrome are generally born preterm and have marked intrauterine polyuria with resultant


Figures 1A and B Electrolyte channels and associated tubular disorders of the
(A) thick ascending limb of loop of Henle and (B) distal convoluted tubule

Abbreviations: NKCC2, Na-K-2CL cotransporter; NCCT, NaCl cotransporter; ClCKb, chloride channel; Paracellin-1, claudin 16; CaSR, calcium-sensing receptor; aBS, antenatal Bartter syndrome; cBS, classic Bartter syndrome; GS, Gitelman syndrome; ADHH, Autosomal dominant hyperparathyroidism; FHHNC, familial hypomagnesemia with hypercalciuria and nephrocalcinosis; HSH, hypomagnesemia with secondary hypocalcemia; IDH, isolated dominant hypomagnesemia.

Table 1 Tubular disorders associated with hypokalemia and metabolic alkalosis

Disorder	Chromosome, locus	Gene product; location	Inheritance	Features
Bartter syndrome (BS)				
• Type 1 (antenatal BS)	*SLC12A1*; 15q15-q21.1	Furosemide-sensitive sodium potassium cotransporter-2 (NKCC2); TALH	AR	Antenatal polyhydramnios, prematurity, hypokalemia, metabolic alkalosis, nephrocalcinosis, failure to thrive
• Type 2 (antenatal BS)	*KCNJ1*; 11q24	ROMK potassium channel; TALH, cortical collecting duct	AR	Same as type 1
• Type 3 (classic BS)	*CLCNKB*; 1p36	Chloride channel, CLCKb; TALH, DCT	AR	Hypokalemia, metabolic alkalosis, failure to thrive, hypercalciuria, no nephrocalcinosis
• Type 4 (antenatal BS with sensorineural deafness)	*BSND*; 1p31	Barttin, a chloride channel; TALH, DCT	AR	Same as type 1, sensorineural deafness
Gitelman syndrome	*SLC12A3*; 16q13	Thiazide-sensitive sodium chloride cotransporter (NCCT); DCT	AR	Hypokalemia, metabolic alkalosis, failure to thrive, hypocalciuria, hypomagnesemia, chondrocalcinosis
Autosomal dominant hypocalcemia with hypercalciuria (ADHH)	*CaSR* activating mutations; 3q13	CaSR; TALH	AD	Childhood onset hypokalemia, alkalosis, failure to thrive, hypercalciuria, low PTH, hypomagnesemia, nephrocalcinosis

Abbreviations: TALH, thick ascending limb of loop of Henle; DCT, distal convoluted tubule; AR, autosomal recessive; AD, autosomal dominant; CaSR, calcium-sensing receptor.

polyhydramnios. Polyuria, up to 12–50 mL/kg/hour, continues postnatally and often results in severe dehydration. Polydipsia, salt-craving, and growth failure are common. Marked hypercalciuria with nephrocalcinosis is consistent with the neonatal form and rare in the classic type. Chronic hypokalemia has been associated with metabolic perturbations and nephropathy.

Laboratory Diagnosis
Sodium and chloride wasting and volume contraction result in release of renin, hyperaldosteronism, kaliuresis, severe hypokalemia (serum potassium 1.5–2.0 mEq/L), hypochloremic metabolic alkalosis and hyperprostaglandism with increase in urinary excretion of prostaglandin E_2. Hyponatremia and hyperuricemia are often associated. Urinary chloride concentration typically exceeds 25–35 mEq/L. Hypercalciuria and nephrocalcinosis are more common in the neonatal type and often persist despite therapy.

Differential Diagnoses
Nonrenal causes of chloride loss such as vomiting and cystic fibrosis can be excluded by the presence of low urinary chloride, less than 10 mEq/L. Patients with type 2 Bartter syndrome may be confused with primary pseudohypoaldosteronism (PHA) type 1 because of similar clinical features in the first weeks of life. Hypomagnesemia is uncommon in Bartter syndrome and necessitates exclusion of Gitelman syndrome.

Management
Treatment primarily aims to correct hypokalemia and volume deficit. Supplementation of potassium as KCl 1–3 mEq/kg/day is done. Additionally potassium-sparing diuretics (spironolactone 10–15 mg/kg/day or triamterene 10 mg/kg/day) may be used. The most effective drugs, however, are prostaglandin synthetase inhibitors, chiefly indomethacin (2–4 mg/kg/day). Careful watch for adverse effects of indomethacin such as nausea, vomiting, abdominal pain, peptic ulcer, and renal or hepatic toxicity is needed.

Outcome
Some patients may show clinical improvement but recurrences may occur. Long-term prognosis is guarded with progression to chronic renal failure in adulthood.

Gitelman Syndrome
This autosomal recessive disorder results from defective functioning of thiazide-sensitive sodium chloride (NaCl) cotransporter NCCT of distal convoluted tubule due to inactivating mutations in its gene *SLC12A3*, locus 16q13 **(Figs 1A and B)**.

Pathophysiology
The syndrome is characterized by hypokalemia, hypocalciuria, metabolic alkalosis, and hypomagnesemia due to defective functioning of NCCT in distal tubules.

Clinical Features
Unlike Bartter syndrome, Gitelman syndrome is generally a milder disease with presentation in late childhood to early adulthood. However, half the patients complain of salt-craving, episodes of muscular cramps, abdominal pain, fatigue and sometimes tetany. Growth retardation and polyuria are mild. Chloride wasting is always less than in Bartter syndrome and urinary excretion of prostaglandin E_2 is normal.

Treatment
Treatment is with oral supplementation of magnesium and potassium chloride.

Outcome
Magnesium supplements are needed lifelong, but overall long-term outcome is excellent with preserved renal functions.

HYPERKALEMIA AND METABOLIC ACIDOSIS
Hyperkalemia (serum potassium more than 6 mEq/L) may result from increased intake, or transcellular shifts but is mostly

caused by decreased renal potassium excretion. Decreased renal potassium excretion could result from reasons extrinsic to the kidney, e.g., mineralocorticoid deficiency, or those intrinsic to kidney such as renal failure and renal tubular disorders that limit potassium excretion. Since potassium excretion increases with decline in glomerular filtration rate (GFR), the effect of aldosterone on the distal and collecting tubules is assessed using transtubular potassium gradient (TTKG), given by the formula:

$$TTKG = \frac{Urine\ potassium \times Serum\ osmolality}{Serum\ potassium \times Urine\ osmolality}$$

Normal values range from 4.1 to 10.5 (4.9 to 15.5 for infants). Values below this range indicate mineralocorticoid deficiency or unresponsiveness. Renal tubular acidosis (RTA) type 1 and 2 are associated with hypokalemia and are discussed in the previous chapter. In this section, we discuss type 4 RTA, disorders of mineralocorticoid associated with hyperkalemia and acidosis.

Mineralocorticoid Deficiency

Type 4 renal tubular acidosis results from inadequate production of or reduced distal tubular responsiveness to aldosterone **(Box 2)**. Absence of aldosterone-mediated sodium reabsorption results in hyperkalemia, which subsequently suppresses renal ammonia production, resulting in a reduction of net acid excretion. This results in a hyperkalemic, hyperchloremic acidosis that may render the urine pH acidic (< 5.5).

Mineralocorticoid (aldosterone) deficiency RTA may result from disorders of the adrenal gland [Addison disease, congenital adrenal hyperplasia (CAH), primary hypoaldosteronism]. These disorders have elevated plasma renin, urinary sodium wasting and preserved renal functions.

Hyporeninemic hypoaldosteronism may result from renal diseases associated with tubulointerstitial damage or destruction of the juxtaglomerular apparatus wherein the renal function may be affected.

Distal tubular receptor insensitivity to aldosterone (PHA) is a rare cause of type 4 RTA associated with elevated plasma renin and aldosterone levels, normal renal function, and salt wasting.

BOX 2 Causes of mineralocorticoid (aldosterone) deficiency or resistance

- Hyper-reninemic hypoaldosteronism (primary adrenal insufficiency or Addison disease)
  - Defects of aldosterone biosynthesis (congenital adrenal hyperplasia): Deficiency of 21-hydroxylase, 11β-hydroxylase, 3β-hydroxysteroid dehydrogenase, aldosterone synthase deficiency
  - Adrenal tuberculosis; necrosis
- Hyporeninemic hypoaldosteronism [pseudohypoaldosteronism (PHA)]
  - Primary PHA
    - *Type 1:* Autosomal dominant renal form, autosomal recessive mutisystem form
    - *Type 2* (Gordon syndrome)
  - Secondary PHA
    - Renal diseases with aldosterone deficiency
    - Obstructive uropathy, interstitial nephritis, sickle cell nephropathy, nephrocalcinosis
- Aldosterone resistance
  - Post-transplantation
  - *Drugs:* Amiloride, spironolactone, ACE inhibitors, heparin, NSAIDs, calcineurin inhibitors.

Clinical Features

Patients with type 4 RTA present with features of hyperkalemia and metabolic acidosis. Nephrocalcinosis and urolithiasis are absent in this disorder. The most common acquired cause of type 4 RTA in children is obstructive uropathy. Inherited causes, particularly CAH secondary to 21-hydroxylase deficiency and the autosomal recessive form of PHA type 1, should be considered in the differential diagnoses in infants presenting with salt loss, hypotension and hyperkalemia. Receptor insensitivity or autosomal dominant PHA type 1 is due to mutation in the collecting tubule mineralocorticoid receptor is a less severe disease and improves with age. Autosomal recessive forms of PHA type 1 are due to defective epithelial sodium channels (ENaC) and present in infancy with life-threatening hyperkalemia, salt wasting, metabolic acidosis, and hypotension. Gordon syndrome (PHA type 2), an autosomal dominant condition, results from mutation in the WNK1 and *WNK4* genes (lysine deficient protein kinase genes). Affected patients present with hypertension, hyperkalemia, hyporeninemia, hypoaldosteronism, metabolic acidosis, and volume expansion that is often responsive to thiazide diuretics.

Differential Diagnosis

Before the diagnosis of RTA is considered, other causes of systemic acidosis, such as diarrhea, inborn errors of metabolism, ingestion, lactic acidosis, diabetes mellitus, and renal failure, should be excluded. The biochemical features of proximal and distal RTA include low serum bicarbonate and potassium levels in association with hyperchloremia. In mineralocorticoid deficiency RTA, systemic acidosis is associated with hyperkalemia. The anion gap in all forms of RTA is usually normal.

Treatment

The goal of treatment is to identify the underlying etiology to guide therapy. Often the cause is not directly treatable, so supplemental alkali therapy is given to correct acidosis and improve growth and bone mineralization. Drug-induced type 4 RTA is treated with discontinuation of the offending medication. In cases due to PHA from obstructive uropathy, adequate urinary tract drainage with normal saline infusion and sodium bicarbonate therapy will correct acidosis. Aldosterone deficiency should be treated with mineralocorticoid (fludrocortisone) replacement. Children with type 4 RTA due to PHA type 1 require salt supplementation and potassium restriction.

Pseudohypoaldosteronism type 2 is treated with thiazide diuretics and salt restriction. Patients with other causes of hyperkalemia and type 4 RTA may respond to symptomatic management of hyperkalemia with dietary restriction. A loop diuretic and/or a cation exchange resin may be required in some cases.

NEPHROGENIC DIABETES INSIPIDUS

Diabetes insipidus (DI) is a condition associated with the passage of large volumes, of dilute urine that results from either too little or no antidiuretic hormone [arginine vasopressin (AVP)] release [central diabetes insipidus (CDI)] or from an inability to respond to AVP in the kidney [nephrogenic diabetes insipidus (NDI)]. In children, NDI is more common than CDI, and is most often acquired. Congenital forms of NDI are more severe and difficult to

treat. X-linked NDI accounts for 90% of all the congenital forms of NDI. Acquired NDI is due to different forms of kidney disease or metabolic derangements **(Table 2)**.

Central diabetes insipidus can be idiopathic, hereditary or caused by intracranial injury or disease. A decrease in urine volume and an increase in urine osmolality occur with the administration of exogenous AVP.

Nephrogenic diabetes insipidus is mostly an X-linked recessive disorder with loss of function or dysfunction mutation of the V2 receptor gene (*AVPR2*; locus Xq28) responsible for the inability to concentrate urine in up to 90% cases despite the presence of AVP in the circulation. Autosomal recessive or autosomal dominant presentations usually represent a defect in aquaporin-2 (*AQP2* gene, locus 12q13)—the water channel normally generated when AVP binds to its receptor on the renal tubule epithelium.

Clinical Features

With any form of DI, the signs and symptoms include: polyuria (urine volume > 6 mL/kg/hour in neonates; > 4 mL/kg/hour or > 2 L/m^2 in children), and polydipsia. The large urine volumes occur despite osmotic, or volume stimuli for AVP release. In the X-linked NDI, the affected males typically present in the newborn period with poor feeding and growth, irritability, recurrent vomiting, and constipation. Severe polyuria and polydipsia manifest within a few months. Older children present with enuresis, constipation, and recurrent episodes of dehydration, hypernatremia, fever. Unlike CDI, mental retardation is seen with variable severity in children with NDI attributed to intracranial calcification. Poor growth, learning and behavioral difficulties, delayed bladder control and a flow uropathy (megaureter and megacystis) may be associated.

Laboratory Diagnosis

Once polyuria is established by measurement of 24 hours urine volume, exclude other causes of solute diuresis by measuring

Table 2 Causes of diabetes insipidus in children

Central diabetes insipidus	Nephrogenic diabetes insipidus
Congenital	*Congenital*
• *Familial:* Autosomal dominant or recessive	• *X-linked recessive:* Xq28 encoding *AVPR2* receptor
• DIDMOAD syndrome—*WFS1* gene defect (chromosome 4p16)	• *Autosomal recessive:* Chromosome 12q13 encoding aquaporin-2 receptor (*AQP2*)
• *Congenital anatomic defects:* Holoprosencephaly, agenesis of corpus callosum, septo-optic dysplasia	• Autosomal dominant
Acquired	*Acquired*
• Trauma, surgery, hemorrhage, thrombosis	• *Renal disease:* Obstruction, renal hypoplasia, dysplasia, polycystic kidney disease, nephronophthisis, medullary cystic disease, urate nephropathy
• *Infection:* Meningitis, encephalitis, *Cryptococcus*	
• *Primary or metastatic tumors:* Lymphoma, leukemia, germinoma, pinealoma, craniopharyngioma	• *Metabolic:* Hypercalcemia, hypokalemia
• *Granulomatous disease:* Tuberculosis, sarcoidosis	• *Drugs:* Lithium, amphotericin B, aminoglycosides, diuretics, ifosfamide, others
• *Drugs:* Phenytoin, carbamazepine, valproic acid, adrenergic drugs	
Idiopathic 10–25%	

serum and urine glucose, calcium and potassium. The first morning urine specific gravity more than 1.010 virtually excludes the possibility of DI. Urine osmolality of more than 800 mOsm/kg with a serum osmolality of less than 270 mOsm/kg also rules out the diagnosis of DI, whereas dilute urine with an osmolality of less than 300 mOsm/kg, and a serum osmolality of more than 300 mOsm/kg effectively establishes the diagnosis. DI, both central and nephrogenic can be partial or complete. Water deprivation test coupled with vasopressin test **(Box 3)** helps to establish the diagnosis and differentiate CDI from NDI **(Table 3)**. Magnetic resonance imaging (MRI) of pituitary is an important tool for assessment of etiology of CDI.

Treatment

Desmopressin [1-deamino-8-D-arginine vasopressin (DDAVP)] is the current drug of choice for long-term therapy of CDI. The recommended dose of DDAVP is 100–1,200 μg/day in three divided doses orally; 2–40 μg once or twice a day intranasally; and, 0.1–1 μg parenterally.

Nephrogenic diabetes insipidus will not respond to exogenous AVP. Reduction in the intake of osmols by salt restriction to

---

BOX 3 Water deprivation and vasopressin test

Water deprivation test
- Fasting begins after dinner, bladder is emptied at 8 am, weight recorded, and blood and urine specimens are collected for osmolality
- Subsequently measure body weight and urine volume hourly; assess for signs of dehydration. Collect urine and blood samples
- The test is discontinued if
  – Duration of water deprivation exceeds 7 hours (4 hours in infants)
  – Weight loss ≥ 5% of body weight
  – Three consecutive hourly urine osmolality values are within 10% of each other
  – At any time plasma osmolality > 300 mOsmol/kg or urine osmolality > 800 mOsmol/kg (> 500 mOsmol/kg for infants)

Vasopressin test
- Vasopressin test is performed to distinguish nephrogenic diabetes insipidus from central diabetes insipidus. Desamino-8-D-arginine vasopressin (DDAVP), desmopressin is administered nasally (5–10 μg in neonates and infants, 20 μg in children) or by a subcutaneous injection 0.5 μg/m^2. Hourly urine collection for osmolality is done over the next 3–4 hours. Following administration of DDAVP, patients with NDI fail to show a rise of urine osmolality, which remains below 200–300 mOsm/kg. Those with CDI and primary polydipsia concentrate urine to varying degrees.

Table 3 Interpretation of water deprivation and vasopressin test

Urine osmolality after water deprivation (mOsmol/kg)	% change in urine osmolality after DDAVP	Interpretation
> 800	Minimal or no change	Normal
< 300	> 50%	CDI
300–800	10–50%	Partial CDI
300–800	< 10%	Partial NDI or primary polydipsia
< 300	< 10%	NDI

Abbreviations: CDI, central diabetes insipidus; NDI, nephrogenic diabetes insipidus.

50–100 mmol/day of NaCl and the reduction in protein intake to 1–1.5 g/kg/day of high-quality protein have been recommended. Adequate water intake and access to water is a must. Diuretic use, specifically hydrochlorothiazide 2–4 mg/kg/24 hours divided two times/day or chlorothiazide 25–50 mg/kg/24 hours divided two times/day along with amiloride 0.2–0.4 mg/kg/day (reduces potassium wasting associated with thiazide diuretics) also reduces polyuria. Indomethacin 0.7–1.5 mg/kg/day reduces GFR, thereby decreases total water loss, but long-term use may be associated with adverse effects.

MAGNESIUM HANDLING BY KIDNEYS

Normal plasma magnesium concentration is kept within narrow limits, 1.7–2.1 mg/dL. Hypomagnesemia (< 1.7 mg/dL) can be caused by low dietary intake, poor gastrointestinal absorption, or excessive urinary excretion. It is often associated with hypocalcemia and hypokalemia. A fractional excretion of magnesium of more than 4% in a child with normal renal function is indicative of renal magnesium wasting. Several inherited tubular disorders are responsible for urinary magnesium wasting **(Table 4)**. Gitelman syndrome has been discussed in the previous section. On a normal diet, the fractional excretion of magnesium is 3–5%, and the healthy kidney has the ability to decrease this to less than 1% in the setting of extrarenal causes of hypomagnesemia. Major renal resorption of magnesium occurs in the proximal tubules (15–20%) and the loop of Henle (65–75%) through paracellular pathways **(Figs 1A and B)**.

Hypomagnesemia

The classic sign of severe hypomagnesemia (< 1.2 mg/dL) is hypocalcemia resulting in increased neuromuscular excitability manifesting as tetany, carpopedal spasm, tremors, muscle cramps or seizures. The hypocalcemia is secondary to parathyroid failure and peripheral parathyroid hormone (PTH) resistance as a result of magnesium deficiency. In addition, cardiac arrhythmias including atrial and ventricular tachycardia, prolonged QT interval may be noted. Hypomagnesemia is frequently associated with other abnormalities including hypocalcemia and hypokalemia. Degree of symptoms may not always correlate with serum levels as magnesium is predominantly intracellular and serum levels do not accurately reflect total body stores.

Differential Diagnosis

The differential diagnosis of hypomagnesemia includes both hereditary forms **(Table 4)** and acquired causes **(Box 4)**.

BOX 4 Causes of acquired hypomagnesemia

Inadequate intake
- Deficient diet, parenteral nutrition without magnesium

Defective gastrointestinal absorption
- Malabsorption (celiac disease, inflammatory bowel disease), chronic diarrhea

Increased urinary losses
- *Diuresis:* Postobstructive, diuretic phase of renal transplantation or acute tubular necrosis
- States of hyperparathyroidism or hyperaldosteronism
- *Drugs:* Diuretics (e.g., loop or thiazide diuretics), antibiotics (e.g., aminoglycosides, amphotericin B, pentamidine), antineoplastic agents (cisplatin), immunosuppressive drugs (e.g., cyclosporine)

Intracellular shift
- Repiratory alkalosis, insulin therapy, hungry bone syndrome postparathyroidectomy, refeeding syndrome of malnutrition.

Table 4 Syndromes associated with magnesium wasting

Disorder	Gene, locus	Gene product; location	Inheritance	Features
Gitelman syndrome	*SLC12A3*, 16q12.3	Thiazide-sensitive NaCl cotransporter (NCCT); DCT	AR	Hypokalemia, metabolic alkalosis, hypocalciuria
Hypomagnesemia with secondary hypocalcemia (HSH)	*TRPM6*, 9q22	*TRPM6;* DCT	AR	Hypocalcemia (secondary to parathyroid failure), calcinosis in heart, kidney, cerebral arteries (seizures, choreoathetosis, speech disturbance)
Isolated dominant familial hypomagnesemia (IDH)	*FXYD2*, 11q23	γ-subunit of Na-K-ATPase; DCT	AD	Variable symptoms, tetany, seizures, hypocalciuria, no hypokalemia or nephrocalcinosis
Isolated recessive familial hypomagnesemia	Not known	Not known	AR	Variable
Familial hypomagnesemia with hypercalciuria and nephrocalcinosis (FHHNC)	*CLDN16*, 3q28	Claudin-16, TALH	AR	Nephrocalcinosis, sensorineural deafness, seizure, progressive renal failure
Familial hypomagnesemia, hypercalciuria, nephrocalcinosis, ocular involvement	*CLDN19*, 1p34	Claudin-19, TALH	AR	Hypocalcemic tetany, nephrocalcinosis, sensorineural deafness, myopia magna, retinitis pigmentosa, nystagmus
Autosomal dominant hypocalcemia with hypercalciuria (ADHH)	Calcium-sensing receptor (*CaSR*) gene 3q13	CaSR activating mutation; TAHL, DCT	AD	Hypocalcemia, hypercalciuria, and polyuria

Abbreviations: TALH, thick ascending limb of loop of Henle; DCT, distal convoluted tubule; AR, autosomal recessive; AD, autosomal dominant.

Laboratory Diagnosis

Evaluation of hypomagnesemia should start with a careful history and physical examination, with particular attention to dietary intake and use of offending medications. Laboratory evaluation should include serum magnesium, phosphorus, calcium, and measures of glomerular and tubular functions. Urinary magnesium quantification is helpful to determine renal versus extrarenal magnesium losses. Fractional excretion more than 4% generally indicates renal magnesium wasting.

Treatment

Oral magnesium replacement is associated with diarrhea due to its cathartic action. In neonates and children, the initial treatment usually consists of 25–50 mg magnesium sulfate (0.1–0.2 mmol magnesium) per kilogram body weight slowly given intravenously (over 20 min) (up to a maximum of 2 g). This dose can be repeated every 6–8 hours or can be followed by a continuous infusion of 100–200 mg magnesium sulfate (0.4–0.8 mmol magnesium) per kilogram body weight given over 24 hours. In the presence of hypocalcemia, this regimen can be continued for 3–5 days. Careful cardiac monitoring in these patients is advised and special caution is required in cases of renal insufficiency.

Seyberth HW, Schlingmann KP. Bartter- and Gitelman-like syndromes: salt-losing tubulopathies with loop or DCT defects. Pediatr Nephrol. 2011;26: 1789-802.

IN A NUTSHELL

1. Bartter syndrome and Gitelman syndrome are rare tubular disorders of electrolyte regulation that result in variable degrees of hypokalemia, metabolic alkalosis, hyponatremia and urinary chloride wasting.

2. Clinical features of Bartter syndrome include polyuria, polydipsia, salt-craving, muscle cramps and failure to thrive.

3. The different types of Bartter syndrome vary by age of onset, severity of symptoms, associated electrolyte abnormalities (including hypomagnesemia) and magnitude of urinary calcium wasting.

4. Gitelman syndrome is a milder disease that is distinguished by the presence of hypomagnesemia and hypocalciuria.

5. Treatment consists of supplementation with KCl (and $MgCl_2$ for Gitelman syndrome). Indomethacin is used in children with Bartter syndrome.

6. Type 4 RTA results in normal anion gap metabolic acidosis and hyperkalemia.

7. Blood pressure may be low, normal or high. Plasma renin and aldosterone levels may be increased or decreased.

8. Obstructive uropathy is the most common acquired cause. Among hereditary forms, CAH secondary to 21-hyroxylase deficiency and autosomal recessive PHA type 1 are important.

9. Mineralocorticoid supplementation as fludrocortisone is useful in patients with CAH and Addison disease. Patients with recessive form of PHA type 1 need lifelong salt supplements. Therapy with thiazides corrects the abnormalities noted in patients with PHA type 2.

10. Nephrogenic diabetes insipidus is more common among children than CDI; acquired causes are more common than congenital.

11. Of the congenital nephrogenic DI, 90% are X-linked recessive type.

12. Water deprivation test and vasopressin test help to establish the diagnosis.

13. Central diabetes insipidus responds to replacement with exogenous AVP, as DDAVP. NDI is resistant to DDAVP and is managed with fluid replacement, diuretics (thiazide and amiloride) and indomethacin.

Chapter 41.16
Renal Calculi
Indira Agarwal

Urinary stone disease is rare in children but when present, is associated with metabolic abnormalities that can lead to recurrent stone disease and significant morbidity. In children its presentation, diagnosis and management may be unique as it may be secondary to a systemic disease, renal disease or infection.

EPIDEMIOLOGY

In India, upper and lower urinary tract stones occur frequently but the incidence shows a wide regional variation. The prevalence is high in Satpura part of Maharashtra, parts of Rajasthan and Punjab which are regarded as the stone belt. In recent years, the epidemiology of urinary stone disease has been changing with improving social conditions, particularly in urban areas of more affluent developing countries.

TYPES OF STONES

Calcium oxalate and calcium phosphate account for 75% of all stones due to major consumption of cereals like millet (high in calcium and phosphate), lack of animal protein and high consumption of oxalate-rich vegetables. Struvite (ammonium magnesium phosphate) accounts for 20% of cases, uric acid 4% and cystine stones (cystine or cystine and calcium) about 1% cases.

PATHOGENESIS

Low intake of fluids causes supersaturation of stone forming salts. Food intake may also predispose to stone formation, e.g., increased dairy intake predisposes to hypercalciuria and animal protein increases uric acid production. Vegetarian diet is rich in oxalate, predisposing to its increased urinary excretion. Hypocitraturia and hypomagnesemia cause increased calcium oxalate supersaturation. High urinary concentrations of calcium, oxalate, uric acid and cystine cause solute excess either due to increased renal excretion or low urine volume. This leads to solute supersaturation and precipitation and formation of crystals that may aggregate into stone. Inhibitors of stone formation include citrate, magnesium and pyrophosphate.

Hypercalciuria

This is the most common metabolic abnormality associated with pediatric renal calculi. It is defined as urinary calcium excretion of greater than 4 mg/kg/day in a child more than 2 years old while ingesting a routine diet. If difficult to obtain 24 hours sample, a spot or total calcium creatinine ratio may be measured. These children may present with hematuria, dysuria, urinary frequency or nephrocalcinosis.

Patients with idiopathic hypercalciuria represent a complex interaction between genetic and environmental factors. Idiopathic hypercalciuria is a monogenic defect secondary to increased intestinal absorption or reduced renal tubular reabsorption of calcium. Secondary causes of hypercalciuria include Dent's disease, Bartter syndrome, Wilson disease, glycogen storage disease type 1a, distal renal tubular acidosis and familial hypomagnesemia. Urinary calcium excretion may be increased in patients with dehydration, immobilization with increased bone resorption, medications such as loop diuretics and glucocorticoids, and large doses of vitamin D. Conditions associated with hypercalcemia, e.g., hyperparathyroidism and sarcoidosis also result in hypercalciuria.

Hyperoxaluria

While urinary oxalate greater than 50 mg/1.73 m²/24 hours is considered significant, normative values vary by age and assay method. Primary hyperoxaluria types I and II are rare autosomal disorders characterized by enhanced conversion of glyoxylate to poorly soluble oxalate resulting in increased serum oxalate and hyperoxaluria. Patients present in early childhood with nephrocalcinosis and/or renal stones and progressive kidney disease. Children with fat malabsorption may have enhanced enteric absorption of oxalate since excess fatty acids bind calcium resulting in less calcium being available to combine with oxalate and prevent its absorption. Children with inflammatory bowel disease, extensive bowel resection, pancreatitis and cystic fibrosis are also at risk for hyperoxaluria and nephrolithiasis. Excessive ingestion of ethylene glycol and ascorbic acid results in increased serum oxalate and hyperoxaluria.

Hyperuricosuria

Increased urinary excretion of uric acid can result from enhanced renal excretion alone or its increased production. Idiopathic hyperuricosuria results from a defect in renal tubular uric acid excretion and is often seen in conjunction with hypercalciuria. Overproduction of uric acid occurs in tumor lysis syndrome, lymphoproliferative and myeloproliferative disorders, rare genetic disorders such as Lesch-Nyhan syndrome (hypoxanthine-guanine phosphoribosyltransferase deficiency) and glycogen storage diseases. A high dietary intake of purines is associated with uric acid nephrolithiasis.

Cystinuria

Cystinuria, an autosomal recessive disorder, is characterized by excessive excretion of the dibasic amino acids—cystine, arginine, lysine and ornithine. It is caused by mutations and/or genomic rearrangements in two genes *SLC3A1* and *SLC7A9*. The colorless flat, hexagonal cystine crystals found in the urinary sediment are diagnostic, but identified only in 20–25% of cases.

Hypocitraturia

Citrate is an inhibitor of calcium oxalate and calcium phosphate crystallization. Hypocitraturia is reported in 10% of children with renal calculi. Children with chronic metabolic acidosis have an increased risk of nephrolithiasis because enhanced proximal renal tubular citrate reabsorption decreases citrate excretion, leading to stone formation.

Infection

Urinary tract infection may be the primary cause of a stone or occurs concomitantly with an underlying metabolic or structural abnormality in 20–25% cases. Functional or anatomic obstruction of the urinary tract predisposes children to stasis and infection, which promote stone formation. Bacteria producing the enzyme urease are strongly associated with pediatric nephrolithiasis and include *Proteus*, *Providencia*, *Klebsiella*, *Pseudomonas* and enterococci. Urease breaks down urea to form ammonium and bicarbonate, which creates a favorable biochemical milieu for the formation of struvite stones (magnesium ammonium phosphate). These stones, which can contain carbonate apatite, tend to branch, enlarge and fill renal calyces, producing a *staghorn* appearance.

Xanthogranulomatous pyelonephritis is a rare, severe chronic infection of the kidney that leads to renal parenchymal destruction and chronic inflammation characterized by lipid-laden macrophages resulting in a nonfunctioning or poorly functioning kidney. Nephrectomy or partial nephrectomy is required to treat these patients.

Structural Abnormalities

Congenital abnormalities that cause urinary stasis are associated with nephrolithiasis. These include medullary sponge disease, autosomal dominant polycystic kidney disease, ureteropelvic junction obstruction, horseshoe kidney, bladder exstrophy, augmentation of the bladder and neurogenic bladder.

CLINICAL FEATURES

Most children with nephrolithiasis present with flank or abdominal pain. Young children may be asymptomatic, stones being detected when abdominal imaging is performed for other purposes. Ureteral stones are painful, since they cause ureteral obstruction; dysuria and urgency may suggest urinary tract infection. Hematuria is the sole symptom or observed with abdominal pain in 30–55%.

DIAGNOSIS

Plain abdominal radiograph detects radiopaque stones (e.g., calcium, struvite and cystine stones) but will miss radiolucent stones (uric acid), small stones and those overlying bony structures. Further, urinary obstruction cannot be detected. Ultrasonography is the most commonly used technique to detect calculi. This modality can detect radiolucent uric acid stones and presence of urinary obstruction. However, the modality is investigator-dependent and is limited in its ability to uncover small stones (< 5 mm), papillary or calyceal stones and ureteral stones. Noncontrast helical computed tomography (CT) is the most sensitive modality to detect renal or ureteral stones. CT also provides detailed information enabling detection of obstruction and/or structural anomalies.

Laboratory Evaluation

Suggested evaluation for etiology of renal calculi is listed in **Box 1**. Examination of the urine sediment is useful if crystals are present and may be identified by their characteristic shape. Cystine crystals are flat and hexagonal, calcium oxalate crystals are pyramid or envelope-shaped, magnesium ammonium phosphate crystals are like coffin lids and uric acid are diamond-shaped. Knowledge of reference values for urinary metabolites is vital while interpreting their excretion **(Tables 1 and 2)**.

MANAGEMENT

Medical Management

Both nonsteroidal anti-inflammatory drugs and opioids are useful in controlling pain associated with nephrolithiasis. Fluid intake should be increased by 150% to reduce the risk of supersaturation and potential for crystallization. *Chemolysis* is the method of maintaining an alkaline urinary pH for acidic stones like uric acid, oxalate and cystine, and an acidic pH for struvite stones, using oral potassium citrate and acid phosphate preparations, respectively. Dietary restriction of sodium is useful in restricting

---

BOX 1 Initial screening for patients with renal stones

- Urine microscopy, culture and sensitivity
- Blood urea, creatinine, sodium, potassium, chloride, calcium, magnesium, bicarbonate, phosphate, uric acid, alkaline phosphatase
- Ultrasound of kidneys, ureter and bladder
- Plain abdominal radiograph
- Stone analysis (if passed or removed surgically)
- Spot urine for ratios of calcium, cystine, oxalate and uric acid to creatinine
- 24 hours urine collection for calcium, sodium, potassium, magnesium, citrate, oxalate, cystine, uric acid and xanthine.

Table 1 Reference ranges for solute excretion in 24 hours urine specimens

Solute	Reference range
Calcium	< 4 mg (0.1 mmol)/kg
Sodium	< 3 mEq (3 mmol)/kg
Potassium	> 3 mEq (3 mmol)/kg
Magnesium	> 88 mg (44 mmol)/1.73 m^2
Citrate	> 180 mg [94 μmol/g (8.84 mmol)] creatinine
Oxalate	< 52 mg (593 mmol)/1.73 m^2; < 2 mg (23 mmol)/kg
Cystine	< 60 mg (0.5 mmol)/1.73 m^2
Uric acid	< 815 mg (4.9 mmol)/1.73 m^2; < 35 mg (0.21 mmol)/kg
Xanthine	30–90 μg (20–60 μmol)

Table 2 Reference range for spot urine samples

Urine constituent	Age	Value, mg/mg creatinine
Calcium: Creatinine	0–6 months	< 0.8
	7–12 months	< 0.6
	≥ 2 years	< 0.21
Oxalate: Creatinine	< 1 year	0.15–0.26

hypercalciuria. Intake of diet rich in calcium and low on oxalate reduces hyperoxaluria. Since urinary tract infections may be associated with nephrolithiasis, urine culture should be obtained if the child is symptomatic and appropriate antibiotic therapy initiated.

Stone Passage

Most stones less than 5 mm in diameter pass spontaneously, even in small children. Hydration increases urinary flow and facilitates stone passage. While alpha-blockers have been used to facilitate stone passage in distal ureteral stones, their routine use is not recommended. Stone analysis provides the stone composition that can guide further evaluation and suggest measures to prevent recurrences. Ultrasonography is used to monitor stone passage, and repeated X-rays or CT scans avoided.

Urological Intervention

The decision to intervene surgically depends on the location, size and composition of stone and the presence of accompanying obstruction and infection. Intervention may be considered if there are signs of infection, complete or partial obstruction, renal insufficiency, or stone greater than 5 mm in diameter. Chief indications are the following:

Unremitting severe pain Pain persisting despite adequate analgesia is usually caused by stone obstructing the ureterovesical or pelviureteric junction. Pain is relieved with a temporizing ureteral stent and subsequent stone removal.

Impaired differential renal function Urinary obstruction causes renal parenchymal injury and decrease in renal function. Intervention in patients with mild renal insufficiency demonstrates improvement in renal function due to relief of obstruction and subsequent recovery of injured renal tissue. The goal of management is thus to minimize renal injury, balancing the risk of the urologic procedure versus harm from continued obstruction.

Struvite calculi These calculi usually require removal in order to eradicate the infection with urease-producing bacteria (e.g., *Proteus* or *Klebsiella*), which is a risk factor for recurrent stone

Table 3 Choice of procedure

Location/Type	Size	Choice of procedure
Lower pole calculi	Any size	Extracorporeal shock wave lithotripsy (ESWL), or ureteroscopy
Radiopaque, in renal pelvis	< 1 cm	ESWL
In renal pelvis	1–2 cm	Percutaneous nephrolithotomy (PCNL), or ESWL
In renal pelvis	> 2 cm	PCNL, ureteroscopy, ESWL
Pelviureteric junction obstruction		PCNL
Calyceal diverticulum		PCNL
Cystine and calcium oxalate monohydrate stones		PCNL, ureteroscopy
Struvite, uric acid or calcium oxalate dihydrate		ESWL

Abbreviations: ESWL, extracorporeal shock wave lithotripsy; PCNL, percutaneous nephrolithotomy.

formation and predisposes to sepsis. Struvite stones are usually too large to pass spontaneously as they tend to branch and fill the renal calyces.

Procedures

Table 3 highlights the choice of procedure according to location/type of calculi.

Extracorporeal shock wave lithotripsy Extracorporeal shock wave lithotripsy (ESWL) employs high energy shock waves produced by an electrical discharge and is effective and safe in children. For stones less than 2 cm in diameter, the resulting fragments are usually passed without difficulty, but may take several months to clear. If the stone is greater than 2 cm in diameter, stents are placed to reduce the risk of obstruction.

Percutaneous nephrolithotomy (*PCNL*) Following percutaneous access to the collecting system, the tract is dilated with a balloon dilator, and the stone is either extracted with a grasping forceps or fragmented with *laser*, ultrasonic, pneumatic or hydraulic lithotripsy probe. PCNL and ESWL can be performed in conjunction.

Ureteroscopy Ureteroscopy is used in pediatric patients as first-line therapy in the management of ureteral calculi as well as following failure of ESWL. Once the stone is visualized, it is extracted with grasping forceps or basket, or fragmented with *laser*, ultrasonic or electrohydraulic lithotripsy. Patients with upper tract stones (stones in the poles of the pelvis) may require multiple sessions and/or ureteral stenting.

IN A NUTSHELL

1. Calcium oxalate and calcium phosphate account for 75% of all stones; struvite (ammonium magnesium phosphate) accounts for 20% of cases, uric acid 4% and cystine stones (cystine or cystine and calcium) about 1% cases.
2. Predisposing factors include structural abnormalities, infection, hypercalciuria, hyperuricosuria, hypocitraturia, and hyperoxaluria.
3. Most children with nephrolithiasis present with abdominal pain and/or hematuria.
4. Ultrasonography is the most commonly used technique to detect calculi.
5. Surgical intervention is considered if there are signs of infection, complete or partial obstruction, renal insufficiency, or stone greater than 5 mm in diameter.

Chapter 41.17
Refractory Rickets
Abhijeet Saha

Calcium and phosphate are required for normal bone growth and mineralization. Impairment in the process of mineralization presents as rickets and/or osteomalacia among children and osteomalacia alone in adults. Failure or delay of mineralization at the unfused growth plates in children results in widening and splaying of the growth plate, with widened wrists, double malleoli, prominent costochondral junctions and bowing of legs. Defect in mineralization of already developed osteoid results in deformed long bones, termed as osteomalacia.

Vitamin D deficiency is the chief cause of nutritional rickets world over, including areas with adequate sun exposure. Whole body clothing, living predominantly indoors and industrial pollution are the chief reasons for limited sun exposure. Other factors include malabsorption and severe calcium deficiency. Therapy for nutritional rickets comprises of administration of vitamin D at a dose of 100,000–600,000 IU (2.5–15 mg) over 1–5 days or 60,000 IU (1.5 mg) every week for 6–8 weeks. Subsequently, 400 IU of vitamin D per day is administered along with calcium at 30–75 mg/kg/day in divided doses for 2–4 weeks. Once levels of parathormone (PTH) and 25(OH)D$_3$ are normal and vitamin D supplementation reduced to 400 IU/day, calcium supplementation is not necessary. Increase in serum phosphate is the first biochemical change seen around 1–2 weeks after high-dose therapy. Radiographic changes of rickets are best sought in rapidly growing bones, such as the distal ulna and metaphyses of knees. Radiologic healing begins within 1 week; complete resolution may take months and a repeat X-ray should be performed after 4 weeks of therapy.

Vitamin D refractory rickets is a clinical condition where child fails to show evidence of radiological healing and correction of biochemical abnormalities despite adequate therapy. Most experts would administer a second dose of vitamin D at 4 weeks if healing of rickets does not occur after first dose, and make a diagnosis of refractory rickets if no healing is observed even after second dose, i.e., after 8 weeks of initiating therapy. Predominant causes of vitamin D refractory rickets include abnormal vitamin D metabolism and defective renal tubular phosphate handling **(Box 1)**.

BOX 1 Etiology of vitamin D refractory rickets

Calcipenic rickets (increased parathormone)
- Vitamin D-dependent rickets type I (1α-hydroxylase deficiency)
- Vitamin D-dependent rickets type II
- Chronic kidney disease

Phosphopenic rickets (normal parathormone)
- Renal phosphate leak with increased fibroblast growth factor 23
  - *Hypophosphatemic rickets:* X-linked, autosomal recessive, autosomal dominant
  - Tumor-induced osteomalacia
  - McCune-Albright syndrome
  - Linear nevus sebaceous syndrome
- Renal phosphate leak with hypercalciuria
  - Distal renal tubular acidosis
  - Hereditary hypophosphatemic rickets with hypercalciuria
  - Dent's disease, Lowe syndrome
- Fanconi syndrome
  - Primary
  - *Secondary:* Cystinosis, galactosemia

ETIOLOGY

Calcipenic rickets is characterized by increased levels of PTH, resulting in internalization of tubular phosphate transporters and impaired phosphate reabsorption. Low plasma phosphate with normal PTH is feature of phosphopenic rickets. This might arise from increased production of fibroblast growth factor 23 (FGF23), a phosphaturic hormone, or from renal tubular disorders resulting in renal phosphate wasting. Renal tubular acidosis (RTA), hypophosphatemic rickets and vitamin D-dependent rickets (VDDR) are common causes of nonazotemic refractory rickets in Indian children.

PATHOPHYSIOLOGY

In the epidermis, 7-dehydrocholesterol (provitamin D) is converted to previtamin D by ultraviolet B waves from the sun. Previtamin D isomerizes to cholecalciferol (vitamin D$_3$) and passes to dermal capillaries where it binds to vitamin D-binding protein. Vitamin D$_3$ is also present in fatty fish (salmon, herring, cod, mackerel, sardine), shiitake mushrooms, liver, cod liver oil and egg yolk. Ergocalciferol (vitamin D$_2$) is consumed as plants and yeast. Vitamin D$_2$ and D$_3$ ingested from food incorporate into micelles in gut enterocytes and are processed into chylomicrons. Vitamin D$_3$ is more potent than vitamin D$_2$ because of a greater affinity for binding proteins; when taken in equivalent doses it causes a greater increase in serum calcidiol, 25(OH)D$_3$. Transportation of vitamins D$_2$ and D$_3$ to the liver is followed by conversion to 25(OH)D$_3$ by the cytochrome *CYP2R1*. Because calcidiol has little feedback effect on its own synthesis, its serum levels approximate body stores of vitamin D. Following filtration, 25(OH)D$_3$ is reabsorbed in proximal tubules, entering mitochondria where it is 1-hydroxylated to the biologically active hormone 1,25(OH)$_2$ vitamin D$_3$ [1,25(OH)$_2$D$_3$] (calcitriol). Cytochrome P450 mono-oxygenase 25(OH) vitamin D-1-α-hydroxylase, encoded by *CYP27B1*, regulates 1,25(OH)$_2$D$_3$ synthesis. It is stimulated by PTH, PTH-related protein, calcitonin, hypocalcemia, hypophosphatemia, growth hormone, prolactin, 24,25(OH)$_2$D and insulin-like growth factor 1. It is suppressed directly by high levels of calcium and phosphorus, inhibitory autofeedback, FGF23, and indirectly by suppression of synthesis of PTH. The biological half-life of calcitriol is 4 hours. Within minutes of binding to its nuclear receptor, calcitriol promotes intestinal absorption of calcium and opening of voltage-gated calcium channels in osteoblasts. Calcitriol stimulates growth plate chondrocytes, increases generation of osteoblasts and type l collagen formation, and suppresses osteoclastic resorption; calcitriol also inhibits transcription of PTH in the parathyroid glands.

Vitamin D-dependent rickets type I, also known as pseudovitamin D deficiency rickets, is an autosomal recessive disease associated with diminished or absent synthesis of 1,25(OH)$_2$D$_3$ due to deficiency of the 25-hydroxyvitamin D$_3$ 1α-hydroxylase enzyme in the kidney. Numerous mutations in the *CYP27A1* gene that encodes 25(OH)D$_3$ 1α-hydroxylase in the kidney have been described. Mutations in the vitamin D receptor gene are the cause of VDDR type II; patients show end-organ resistance to vitamin D.

Tubular reabsorption of phosphate is carried out by sodium-coupled phosphate (NaPi) cotransporters localized at the apical membrane of tubular cells. The cotransporters NaPi-IIa and NaPi-IIc are expressed in the proximal brush border membranes. NaPi-IIa transporter is the key mediator of proximal phosphate reabsorption. Dietary phosphate is absorbed through the small intestine, predominantly in the jejunum. To maintain balance, the amount of phosphate absorbed in the intestine is similar to

the amount excreted in the urine. This balance is maintained and closely regulated by the coordinated actions of hormones, including osteocyte-derived FGF23, PTH and $1,25(OH)_2D_3$ **(Fig. 1)**.

Phosphate wasting in hypophosphatemic rickets is associated with elevated FGF23. FGF23 causes phosphaturia by downregulating NaPi-IIa and NaPi-IIc in proximal renal tubules; it also inhibits 25(OH) vitamin D 1α-hydroxylase, promotes 25(OH) D 24-hydroxylase and inhibits PTH secretion. The X-linked form of hypophosphatemic rickets (XLHR) is mediated by loss-of-function mutations in *PHEX*, an endopeptidase encoded by a gene on X chromosome. The autosomal dominant form is associated with heterozygous mutations that impair degradation of FGF23; the recessive type involves loss of function mutations in dentin matrix protein 1 or ecto/nucleotide pyrophosphatase/phosphodiesterase 1 that inhibit production of FGF23. Rarely, mesenchymal tumors secrete excess amounts of FGF23 leading to tumor-induced osteomalacia.

CLINICAL FEATURES

Rickets initially manifests at the distal forearm, knee and costochondral junctions as these are the sites of rapid bone growth and mineralization. Hypoplasia of the dental enamel is common in calcipenic rickets. Patients with VDDR type I present in early infancy with muscle weakness, rickets and hypocalcemic seizures. Physical examination may show positive Trousseau and Chvostek signs. VDDR type II is characterized clinically by an early onset of rickets, poor linear growth, alopecia, epidermal cysts and loss of teeth.

Features of hypophosphatemic rickets include bowing of legs, muscle weakness, bone pain and short stature. Deformity of legs is noted with the onset of walking. Defective dentin formation results in dental abscesses and loss of teeth. Clinical findings are limited to legs and findings like rachitic rosary and wrist widening are usually absent. XLHR may be associated with hearing impairment that is apparent in adulthood.
Figure 1 Phosphorus homeostasis. Serum concentrations of phosphate (P) depend on intestinal absorption, renal elimination and release from bone. These processes are regulated by serum parathormone (PTH), fibroblast growth factor 23 (FGF23) produced by osteocytes and $1,25(OH)_2D_3$. PTH and FGF23 reduce levels of phosphate, while $1,25(OH)_2D_3$ increases these levels (green arrowheads). Secretion of these hormones is in turn regulated by reciprocal interplay and by feedback of serum levels of calcium (Ca) and P

Features of RTA include growth failure, polyuria, polydipsia and preference of savory food. Patients with proximal RTA have either isolated bicarbonaturia or Fanconi syndrome (glucosuria, aminoaciduria, phosphaturia, uricosuria and bicarbonaturia) secondary to cystinosis, galactosemia, tyrosinemia, Wilson disease or Lowe syndrome. Manifestations of distal RTA are growth impairment, polyuria, nephrocalcinosis, nephrolithiasis and symptoms due to hypokalemia. Distal RTA in children is usually primary; rare cases are secondary to systemic lupus erythematosus or Sjögren syndrome. Children with chronic kidney disease have growth retardation, bone deformities and anemia.

DIFFERENTIAL DIAGNOSIS

Some systemic diseases have features similar to rickets. Hypophosphatasia is characterized by disordered mineralization of bones secondary to deficient tissue nonspecific alkaline phosphatase activity, resulting from loss of function mutations in the liver/bone/kidney alkaline phosphatase gene. Six clinical forms are recognized that vary in severity and age at onset. Deformities noted in the childhood variant include enlarged joints, dolichocephaly, short stature and waddling gait. Signs of intracranial hypertension, failure to thrive, fractures and bone pain are common. Radiographs show widespread demineralization and rachitic changes at ends of metaphysis. Low serum levels of alkaline phosphatase and increased urinary phosphoethanolamine support the diagnosis.

Fluorosis is endemic in many Asian countries including China and India. High levels of fluorine are reported in drinking water from Seemandhra, Telangana, Gujarat and Rajasthan. Bony deformities and radiological features mimic rickets. Dental caries is common. Serum levels of alkaline phosphatase and PTH are raised. Urinary levels of fluoride are high.

APPROACH TO DIAGNOSIS

Radiological signs of rickets include splaying, fraying, cupping and demineralization of the distal radial and ulnar metaphyses along with widening of the physis. Investigations include serum levels of calcium, phosphate, PTH, $25(OH)D_3$, $1,25(OH)_2D_3$, renal functions tests and venous blood gas. Phosphaturia should be assessed by calculation of tubular reabsorption of phosphate and maximal tubular reabsorption of phosphorus per glomerular filtration rate (TmP/GFR). Urine is analyzed for calcium, phosphate and creatinine on timed and spot specimens. The presence of sugar, albumin and aminoaciduria suggests Fanconi syndrome; aminoaciduria is also seen in patients with VDDR type I. Patients with metabolic acidosis need evaluation to diagnose and characterize RTA (*See* Chapter 41.14).

Vitamin D deficiency is characterized by low levels of phosphorus and 25(OH) vitamin D_3; levels of PTH and alkaline phosphatase are raised. Since secondary hyperparathyroidism may cause phosphaturia, the TmP/GFR is estimated after vitamin D levels are corrected. **Table 1** shows important alterations in various forms of rickets. An algorithm for evaluation is depicted in **Flow chart 1**.

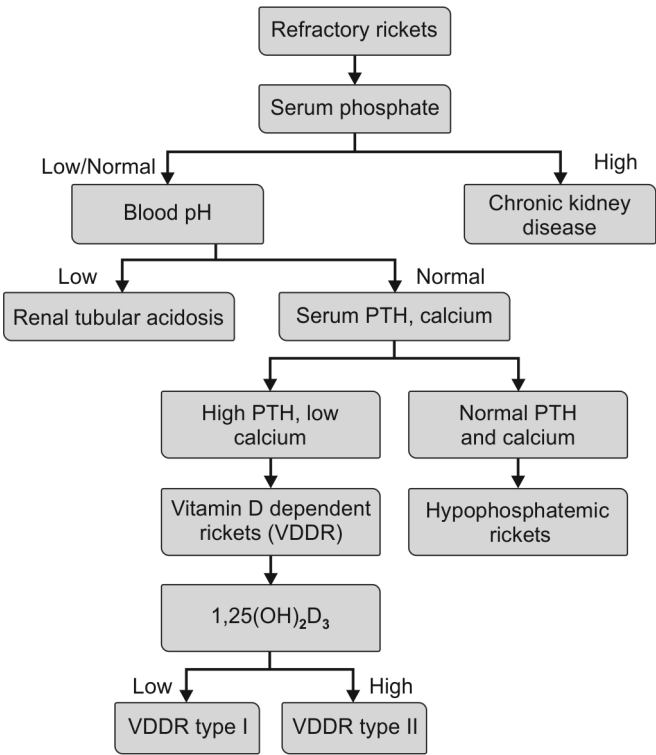
MANAGEMENT

Patients with hypophosphatemic rickets need oral phosphorus supplementation at 40–60 mg/kg/day in the form of neutral phosphate solution or tablets or Joulie's solution. The use of multiple daily doses is advised as serum phosphate levels return to low baseline values within a few hours of phosphate supplementation.

Table 1 Laboratory diagnosis of rickets

	Calcium	Phosphorus	Alkaline phosphatase	Parathormone	25(OH) vitamin D	1,25(OH)$_2$ vitamin D	Urinary calcium	TmP/GFR
Vitamin D deficiency	N or ↓	↓	↑	↑	↓	N or ↑	↓ or N	
Calcium deficiency	↓	↓	↑	↑	N	↑	↓	
VDDR type I	↓	↓ or N	↑↑	↑	N	↓↓	↓	
VDDR type II	↓	↓ or N	↑↑	↑	N	↑↑	↓	
Hypophosphatemic rickets								
X-linked	N	↓	↑	N	N	N or ↓	↓	↓
Autosomal dominant	N	↓	↑	N	N	N	N	↓
With hypercalciuria	N	↓↓	↑	N or ↓	N	↑	↑	↓
Fanconi syndrome	N	↓	N or ↑	N or ↑	N	N or ↓	N or ↑	↓
Chronic kidney disease	↓	↑	↑	↑	↓	↓	↓	

Abbreviations: TmP/GFR, ratio of the maximum rate of tubular phosphate reabsorption to the glomerular filtration rate; VDDR, vitamin D-dependent rickets.

Flow chart 1 Diagnostic approach to refractory rickets


In addition, an active form of vitamin D (1–2 μg/day alfacalcidol or 0.5–1 μg/day calcitriol) is necessary to counter the 1,25(OH)$_2$D$_3$ deficiency. The dose of vitamin D analog is increased during periods of increased growth velocity and decreased after healing of rickets; the dose is titrated to achieve normal levels of alkaline phosphatase, improve bowing and growth velocity, while avoiding hypercalciuria. Patients with hereditary hypophosphatemic rickets with hypercalciuria show increased 1,25(OH)$_2$D$_3$ synthesis and suppression of PTH; these patients require treatment with phosphate supplements alone. Optimal therapy is indicated by the

resolution of bone pains (within a few weeks), return to normal of levels of alkaline phosphatase (within a few months), increase in growth velocity (in a year) and straightening of legs (in 3–4 years). Increased PTH levels suggest overtreatment with phosphate or under treatment with vitamin D analog. Persistence of leg bowing persists despite *optimal* treatment requires consideration of surgery, preferably beyond growing age.

Patients with VDDR type I require physiological doses of alfacalcidol or calcitriol (1–3 μg/day) along with calcium supplements. Improvement in serum calcium occurs within days, radiologic improvement within 2–3 months while the rickets heals by 9–10 months. Treatment of VDDR type II is challenging with variable response. While some patients respond to very large doses of calcitriol and calcium supplementation, others require prolonged administration of intravenous (IV) calcium to bypass the defect in intestinal calcium absorption. The use of IV calcium may be useful in ameliorating hypocalcemia, hypophosphatemia, secondary hyperparathyroidism and elevated alkaline phosphatase. Phosphate supplements are not required if correction of serum calcium results in improvement in secondary hyperparathyroidism that causes hypophosphatemia. The calcimimetic, cinacalcet has been recently used to control secondary hyperparathyroidism in VDDR type II leading to healing of rickets.

Therapy for RTA is detailed in Chapter 41.14. Patients with distal RTA must receive alkali supplementation as sodium and/or potassium bicarbonate or citrate salts (Polycitra, Shohl's solution) to maintain serum bicarbonate (HCO$_3^-$) concentration greater than 20–22 mEq/L. The requirement of alkali typically decreases from 5–8 mEq/kg/day in infancy to 3–4 mEq/kg/day in childhood and 1–2 mEq/kg/day in adults. Compliance is hindered by the need for multiple daily doses and bitter taste of the citrate solution; palatability is improved by mixing it with water or juice. The excessive use of sodium bicarbonate is counterproductive since it expands extracellular volume and decreases proximal tubular reabsorption of HCO$_3^-$, thereby increasing the need for alkali. Normalization of serum HCO$_3^-$ concentration and growth are good indicators of appropriate treatment. Patients with proximal RTA require alkali at 5–8 mEq/kg/day along with dietary sodium

restriction, and occasionally, hydrochlorothiazide. Patients with Fanconi syndrome require additional phosphate supplementation.

IN A NUTSHELL

1. Vitamin D refractory rickets is a clinical syndrome where there is lack of bone mineralization despite adequate therapy with vitamin D.
2. Clinical signs of refractory rickets include growth failure, bony deformities, bone pain, muscle weakness, polyuria, polydipsia and dental caries.
3. Common causes of nonazotemic refractory rickets in children include RTA, hypophosphatemic rickets and VDDR type I and II.
4. Adequate treatment is associated with satisfactory response in most cases.

Chapter 41.18
Hypertension
Swasti Chaturvedi

Hypertension is a risk factor for stroke, coronary artery disease and kidney damage in adults. There is a paucity of data about the long-term sequelae of persistent hypertension in children, but it is known that children with hypertension have evidence of end-organ damage and are at risk of hypertension into adulthood. The widespread adoption of National High Blood Pressure Education Program Fourth Report has led to uniformity in classification and management of hypertension. The Indian Society of Pediatric Nephrology (ISPN) has provided guidelines for systematic and careful evaluation of hypertensive children. The incidence of primary hypertension is estimated to be 1–20% and rising among children and young adults.

DEFINITION OF HYPERTENSION

The definition of hypertension in adults is based on the extensive morbidity and mortality data. This allowed correlation of high blood pressure in adults with the adverse events thus making it possible to have relevant *cut-off* measurements. As mentioned previously, there is a paucity of long-term studies looking at effects of pediatric hypertension and hence definitions are just based on normative distribution of systolic and diastolic blood pressure in healthy children **(Table 1)**. This table includes the 50th, 90th, 95th and 99th percentiles by gender, age and height.

Measurement of Blood Pressure

Blood pressure should be measured routinely, at least annually, in all children older than 3 years who seek medical consultation. Children below 3 years with any of the following risk factors should also be screened for hypertension: (1) history of prematurity, very low birthweight babies, or other neonatal complications requiring intensive care; (2) congenital heart disease (repaired or unrepaired); (3) recurrent urinary tract infections, hematuria, or proteinuria; (4) known renal disease or urologic malformation; (5) family history of congenital renal disease; (6) solid organ transplantation; (7) malignancy or bone marrow transplant; (8) treatment with drugs known to raise blood pressure; (9) other illnesses associated with hypertension, e.g., neurofibromatosis, tuberous sclerosis; and (10) evidence of raised intracranial pressure.

Method of Measurement and Devices

Various measurement devices are available. The auscultatory method is preferred, and performed using either the mercury or aneroid sphygmomanometer. The use of the former is discouraged due to the environmental toxicity of mercury. The aneroid sphygmomanometers are quite accurate but need regular calibration. The oscillometric devices measure mean arterial pressure and then use algorithms to calculate systolic and diastolic blood pressure. Advantages of these instruments are their ease of use (especially in infants and younger children and in intensive care setting), no environmental hazard and minimization of observer bias. The disadvantages are that the algorithms used by companies are proprietary and differ among devices; this can result in variations and lack of comparability. These devices also need regular validation and calibration. Blood pressure values exceeding the 90th centile by oscillometric method should be confirmed by an auscultatory technique.

Ambulatory Blood Pressure Monitoring

Blood pressure demonstrates a circadian rhythm and is affected by sleep/wake cycle and activity. A single random blood pressure level thus may not be truly representative; ambulatory blood pressure monitoring (ABPM) provides a more detailed overview. A portable device records systolic and diastolic blood pressure every 20–30 min over 24 hours. Parents or child are instructed to maintain a diary with record of the time of sleeping and time of waking and any activity. The mean blood pressure during the day and night and over 24 hours as well the degree to which blood pressure exceeds the upper limit of normal over a time period (blood pressure load > 25% is considered abnormal) are calculated. Additionally ABPM can detect the phenomenon of *dipping*, the normal physiological drop in blood pressure during sleep. Absent or reduced dipping (< 10%) is seen in children with chronic kidney disease. ABPM is indicated in patients with suspected white coat or masked hypertension, in assessing hypertension risk and if detailed information regarding blood pressure patterns is required (patients with episodic hypertension, chronic kidney disease, diabetes mellitus and autonomic dysfunction).

ETIOLOGY

Hypertension can be primary (essential) or secondary to a renal, cardiac, vascular or endocrine cause. Secondary causes are likely in a younger child and in presence of stage 2 hypertension. Renal parenchymal causes account for 75% and renovascular causes for 10% of secondary hypertension **(Table 2)**. Renal parenchymal disease includes conditions like acute or chronic glomerulonephritis, reflux nephropathy and obstructive uropathy. Renovascular disease may occur due to renal artery stenosis, renal artery thrombosis or Takayasu aortoarteritis. Endocrine causes include pheochromocytoma, neuroblastoma, primary hyperaldosteronism, Cushing syndrome

Table 1 Staging of pediatric hypertension

	Definition
Normal blood pressure	Average systolic or diastolic blood pressure < 90th percentile
Prehypertension	Average systolic or diastolic blood pressure 90th to 95th percentile, or blood pressure > 120/80 mm Hg
Stage 1 hypertension	Average systolic or diastolic blood pressure 95th to 99th percentile plus 5 mm Hg
Stage 2 hypertension	Average systolic or diastolic blood pressure > 99th percentile plus 5 mm Hg
White coat hypertension	Blood pressure > 95th centile when measured in clinic setting but < 90th centile when measured outside clinic environment. This appears to be a prehypertensive condition with risk of ventricular hypertrophy and progression to sustained hypertension
Masked hypertension	Blood pressure normal in clinic setting but in hypertensive range when measured outside clinic environment as detected on ambulatory blood pressure monitoring. This condition is considered more serious than white coat hypertension
Hypertensive urgency	Raised blood pressure without end-organ damage or symptoms, such as headache, nausea or blurred vision
Hypertensive emergency	Raised blood pressure along with presence of end-organ damage, such as encephalopathy, seizures, congestive heart failure, acute kidney injury, papilledema or pulmonary edema

Note that normative data is based on age, height and gender. Definitions are based on blood pressure taken on greater than or equal to three separate occasions. The addition of 5 mm Hg to define stage 2 hypertension is to allow for interobserver differences. Blood pressure tables are applicable for children aged 1 year and older, and should be used when measuring blood pressure by auscultatory method. Normative data for oscillometric devices is also available.

Table 2 Causes of persistent hypertension by age

Newborn	Childhood	Adolescence
Renal vein thrombosis	Renal parenchymal disease (dysplasia, glomerular)	Primary (essential) hypertension
Coarctation of aorta	Renovascular disease	Renal parenchymal disease
Congenital renal anomalies	Coarctation of aorta	Renovascular disease
Renal artery stenosis	Endocrine causes	Endocrine causes
	Primary (essential) hypertension	

and hyperthyroidism. Primary hypertension is a diagnosis of exclusion when no etiology is identified after careful evaluation.

CLINICAL FEATURES

Hypertension is mostly asymptomatic in children. Clinical history taking and examination **(Table 3)** for the underlying etiology should be focused on detecting secondary causes.

INVESTIGATIONS

A careful history and examination is complemented by judicious and targeted use of investigations to identify the cause.

Preliminary Investigations
- Complete blood counts
- Blood electrolytes, creatinine, urea, calcium, phosphorus, bicarbonate, uric acid; urinalysis, urine culture, 24 hours protein
- Chest X-ray, abdominal ultrasound
- Screen for end-organ damage and comorbidities: ECG, echocardiogram, fundus examination, fasting lipid profile and glucose.

Further Investigations

Glomerulonephritis Serum C3, antistreptolysin-O titer (ASO), antinuclear antibody (ANA), anti-double-stranded DNA (anti-dsDNA), antineutrophil cytoplasmic autoantibody (ANCA), renal biopsy.

Reflux nephropathy Micturating cystourethrogram, dimercapto-succinic acid scintigraphy.

Renovascular disease Doppler ultrasound, captopril-primed isotope scintigraphy (DTPA or MAG3), renal angiography or digital subtraction angiography, renin sampling from renal veins and inferior vena cava.

Pheochromocytoma Urine and plasma catecholamines, calcitonin, parathormone, metaiodobenzylguanidine (MIBG) scintigraphy, CT and magnetic resonance imaging.

Endocrine causes Urine steroid profile; plasma renin, aldosterone, cortisol, dexamethasone and adrenocorticotropic hormone (ACTH) tests.

Coarctation of aorta Echocardiogram, angiography.

Rarely, single gene disorders can lead to hypertension **(Table 4)**. These conditions should be suspected when there is strong family history, severe and difficult to control hypertension, and presence of electrolyte and acid-base abnormalities.

TREATMENT

Therapy of hypertension depends on severity and cause of hypertension. In general prehypertension and stage 1 hypertension

Table 3 Clues to etiology based on findings on physical examination

Clinical examination	Finding	Possible cause
Height, weight	Growth delay	Chronic illness
Body mass index	Elevated	Obesity in an adolescent suggests primary hypertension; truncal obesity is seen with cushing disease
Heart rate	Tachycardia	Hyperthyroidism, pheochromocytoma, neuroblastoma, primary hypertension
Four limb pulses and blood pressure	Decreased lower limb pulses; low lower extremity pressures	Coarctation of aorta
Eyes	Retinal changes, papilledema	Indicate severe and sustained hypertension
Head and neck	Hirsutism and moon facies	Cushing disease
	Elfin facies	Williams syndrome
	Enlarged thyroid	Hyperthyroidism
	Webbed neck	Turner syndrome
	Tonsil, adenoid hypertrophy	Obstructive sleep apnea
Skin	Pallor, flushing, diaphoresis	Pheochromocytoma
	Rash	Connective tissue disease
	Café-au-lait spots, adenoma sebaceum	Neurofibromatosis, tuberous sclerosis
	Acanthosis nigricans	Type 2 diabetes; metabolic syndrome
Joints	Swelling or tenderness	Connective tissue disease
Chest	Widely spaced nipples	Turner syndrome
	Murmur	Congenital heart disease
Abdomen	Mass	Cystic kidneys, hydronephrosis, Wilms tumor, neuroblastoma
	Bruit	Renal artery stenosis
Genitalia	Ambiguous	Congenital adrenal hyperplasia

Table 4 Monogenic causes of hypertension

Condition	Description	Renin/aldosterone	Potassium	Treatment
Liddle syndrome	Gain of function mutation in ENaC; AD; onset in third decade	Low/low	Low to normal	Amiloride, triamterene
Gordon syndrome	Mutations in gene encoding WNK kinases 1 and 4; AD; onset in second or third decade	Low/low	High, metabolic acidosis	Thiazides, low sodium diet
Glucocorticoid remediable hypertension	Chimeric gene formed from 11β-hydroxylase gene and aldosterone synthase gene results in ACTH stimulating aldosterone synthesis; AD; onset in second or third decade Risk of hemorrhagic stroke from ruptured cerebral aneurysms. Urinary levels of 18-oxosteroids are increased	Low/high	Low to normal	Glucocorticoids
Apparent mineralocorticoid excess	Mutation in gene encoding 11β-hydroxysteroid dehydrogenase; AR; onset in childhood. Nephrocalcinosis and rickets may be noted Ratio of cortisol to cortisone metabolites in the urine is increased	Low/low	Low to normal	Spironolactone, dexamethasone
Congenital adrenal hyperplasia	11β-hydroxylase and 17α-hydroxylase deficiency; AR; onset in childhood	High/high	Low to normal	Glucocorticoids

Abbreviations: ACTH, adrenocorticotropic hormone; AD, autosomal dominant; AR, autosomal recessive; ENaC, epithelial sodium channel.

require institution of nonpharmacological management whereas stage 2 hypertension requires both pharmacological and nonpharmacological management. Hypertensive urgencies and emergencies require urgent recognition and careful lowering of blood pressure in a hospital setting. Surgical treatment is indicated for coarctation of aorta, pheochromocytoma, other endocrine tumors and most forms of renovascular hypertension. **Table 5** outlines the management strategy for children after initial clinic screening.

Nonpharmacological Interventions

Weight reduction results in reduction in systolic and diastolic blood pressure by approximately 1 mm Hg/kg lost; pronounced blood pressure reduction is seen in those with weight loss exceeding 5 kg. Weight loss is associated with an increase in high-density lipoproteins and reduction in triglycerides. Abnormal weight gain should be prevented. *Regular physical exercise* for 30–60 min on most days lowers both systolic and diastolic blood pressures. Sedentary activities should be limited to less than 2 hours a day. *Dietary modification* to consume a low fat and low salt diet is useful. At least five helpings of fruits and vegetables are recommended. The entire family should be involved in lifestyle modifications to have a consistent and sustained effect.

Pharmacological Interventions

Indications of drug therapy are: (1) symptomatic hypertension; (2) secondary hypertension; (3) stage 1 hypertension refractory to lifestyle changes; (4) stage 2 hypertension; and (5) end-organ involvement (proteinuria, retinopathy, left ventricular hypertrophy). Targets for blood pressure reduction depend on the absence or presence of end-organ damage. In the former, the target is to reduce blood pressures to below the 95th percentile, while in the latter the aim is below the 90th percentile.

Hypertensive Emergencies

Prior to commencing antihypertensive therapy, it is important to ensure that elevated blood pressure is not caused by severe pain, increased intracranial pressure or coarctation of aorta because lowering of blood pressure will need to be achieved by different means in these conditions. In patients with hypertensive emergencies, the aim is to reduce blood pressure by 25% during the initial 8 hours of treatment. Excessive reduction should be avoided, since this can result in reduced cerebral blood flow. Accurately titrated intravenous infusions are preferred over oral agents **(Table 6)**.

Pharmacological Agents

Legislative initiatives in the United States and European Union have resulted in increased number of trials on pediatric antihypertensive agents and approval for their use **(Table 7)**.

A recent Cochrane meta-analysis on pharmacological interventions for hypertension found few randomized controlled trials in children. Most studies are of short duration (few weeks) and variable quality. In the absence of good quality evidence, there is no consensus on optimal first-line therapy.

Therapy should be preferably started with a single agent and the dose optimized to achieve the desired reduction in blood pressure. Most experts start with an angiotensin-converting enzyme inhibitor, calcium channel blocker or beta-blocker after ruling out any contraindications to these medications. If a single drug fails to achieve the desired effect then a second drug should be added in a stepwise approach. The antihypertensive agent can be targeted to underlying condition. Some examples of the targeted approach are given in **Table 8**. Drugs affecting the renin-angiotensin-aldosterone system are preferred in children with chronic kidney disease and proteinuria because of renoprotective and antiproteinuric effects.

Table 5 Follow-up after initial blood pressure measurement

	Measure blood pressure	Lifestyle
Normal	Next visit	Normal
Prehypertension	In 6 months	Weight management, physical activity
Stage 1 hypertension	1–2 weeks	Weight management, physical activity
Stage 2 hypertension	Evaluate; refer	Weight management, physical activity

Table 6 Medications used in hypertensive emergencies

	Dose	Side effects
Sodium nitroprusside	0.5–8 μg/kg/min IV infusion	Nausea, arrhythmias, muscle twitching, headache, tachycardia, cyanide toxicity (if used > 72 hours or in renal failure)
Labetalol	0.5–3 mg/kg/hour IV	Pallor, bradycardia; avoid in asthma, heart failure
Esmolol	Load 500–600 μg/kg/min followed by 50–250 μg/kg/min	Blurred vision, confusion, dizziness, increased sweating; avoid if suspected pheochromocytoma
Nifedipine	0.25–0.5 mg/kg oral or sublingual	Flushing, headache, unpredictable hypotension
Hydralazine	0.1–0.5 mg/kg/dose IV slow; can be repeated in 4 hours	Tachycardia, palpitations, flushing, fluid retention

Table 7 Antihypertensive agents

Drug	Dose (oral doses unless specified)	Side effects, comments
Angiotensin-converting enzyme inhibitors (ACEIs)		
Enalapril	0.1–0.6 mg/kg/day QD or BID (max: 40 mg/day)	Cough, angioedema, hyperkalemia; watch for rise in creatinine; avoid use in bilateral renal artery stenosis. Contraindicated in pregnancy: risk of renal tubular dysgenesis, defective skeletal development, death in utero
Benazepril	0.2–0.6 mg/kg/day QD (max: 40 mg/day)	
Lisinopril	0.05–0.6 mg/kg/day QD (max: 40 mg/day)	
Fosinopril	0.1–0.6 mg/kg/day QD (max: 40 mg daily)	
Captopril	0.3–0.5 mg/kg/dose BID or TID	
Angiotensin receptor blockers (ARBs)		
Losartan	0.75–1.4 mg/kg QD (max: 100 mg daily)	Hyperkalemia; watch for rise in creatinine
Irbesartan	75–150 mg/day QD	
Valsartan	1.3–2.7 mg/kg/day QD (max: 160 mg/day)	
Aldosterone receptor antagonist (ARA)		
Eplerenone	25–100 mg/day QD or BID	Hyperkalemia
Beta-blockers		
Atenolol	0.5–2 mg/kg/day QD (max:100 mg/day)	Bradycardia, syncope, lethargy, irritability, depression. Contraindicated in diabetes mellitus, asthma, congestive heart failure, Raynaud phenomenon and atrioventricular septal defects
Propranolol	1–4 mg/kg/day BID-QID (max: 640 mg/day)	
Metoprolol	1–6 mg/kg BID (max: 200 mg/day	
Alpha-blockers		
Prazosin	50–100 μg/kg/day BID-TID (max dose 500 μg/kg/day)	First dose postural hypotension. Phenoxybenzamine and phentolamine are used mostly in pheochromocytoma
Terazosin	0.04–0.4 mg/kg/daily	
Phenoxybenzamine	0.2–0.5 mg/kg BID-TID	
Phentolamine	15 mg/kg in 50 mL dextrose at 1–10 mL/hour IV	
Alpha- and beta-blockers		
Carvedilol	0.1–0.5 mg/kg/dose BID	Pallor, bradycardia; avoid in asthma, heart failure
Labetalol	2–10 mg/kg/day BID	
Calcium channel blockers (CCBs)		
Amlodipine	0.06–0.3 mg/kg/day QD (max: 10 mg/day)	Edema, headache, flushing, tachycardia
Felodipine	2.5 mg/day QD	
Vasodilators		
Hydralazine	0.25–7.5 mg/kg/day TID-QID (max: 200 mg/day)	Tachycardia, headache, salt and water retention; hirsutism with minoxidil
Minoxidil	0.1–1 mg/kg/day BID-TID (max: 50 mg/day)	
Central α-antagonist		
Clonidine	5–20 μg/kg/day QD-BID	Rebound hypertension, hallucinations, depression, sedation, dry mouth
Diuretics		
Hydrochlorothiazide	1–3 mg/kg QD-BID (max: 50 mg/day)	Electrolyte abnormalities, dehydration
Furosemide	0.5–6 mg/kg/day QD-BID	
Amiloride	5–20 mg/day QD	

Abbreviations: BD, twice daily; QD, once daily; QID, four times a day; TID, thrice a day.

Table 8 Suggested choice of antihypertensive drugs based on underlying etiology

Conditions	Medication
Renovascular hypertension	ACEI, ARB, diuretics; ACEI/ARB contraindicated in bilateral renal artery stenosis
Chronic kidney disease with proteinuria, diabetes mellitus with microalbuminuria, obesity related hypertension	ACEI, ARB
Coarctation of aorta, migraine	Beta-blockers
Hypertension related to fluid overload, e.g., acute postinfectious glomerulonephritis	Diuretics (furosemide), CCB; avoid potassium-sparing diuretics and ACEI or ARB in oliguria or severe acute kidney injury

Abbreviations: ACEI, angiotensin-converting enzyme inhibitor; ARB, angiotensin receptor blocker; CCB, calcium channel blocker.

IN A NUTSHELL

1. The prevalence of childhood hypertension is increasing.
2. Patients with confirmed hypertension should be evaluated carefully to identify the underlying etiology, determine comorbidities and detect target-organ damage.
3. Therapeutic lifestyle modification should be advised in all hypertensive children.
4. Pharmacologic therapy is required in those with secondary hypertension, stage 2 or symptomatic hypertension and in the presence of end-organ damage.
5. Since there is no consensus on the first-line antihypertensive agent, medications should be prescribed rationally based on the underlying cause and risk of side effects.

Chapter 41.19
Urinary Tract Infection and Vesicoureteric Reflux
Pankaj Hari

URINARY TRACT INFECTION

About 2–8% of children suffer from urinary tract infection (UTI) and one-third of children with febrile UTI have vesicoureteric reflux (VUR). It is estimated that approximately 1% of children have VUR, increasing the risk of recurrent UTI. Experimental data suggests that UTI in the presence of VUR causes renal scarring. Renal damage associated with VUR accounts for 7–17% of end-stage renal disease. Early recognition and appropriate management of VUR is expected to prevent development of renal insufficiency.

EPIDEMIOLOGY

The incidence of symptomatic UTI in term and preterm neonates is 1% and 3%, respectively. While girls are more prone to UTI than boys, boys are more susceptible before the age of 3 months. It is estimated that 2% of boys and 7% of girls have one UTI by 7 years. The rate of UTI in uncircumcised boys is several fold higher than in circumcised boys.

ETIOLOGY

Over 80% of community-acquired UTI is caused by *Escherichia coli*. Organisms such as *Klebsiella*, *Proteus*, *Enterobacter*, *Staphylococcus* and *Streptococcus faecalis* are identified in immunocompromised hosts, patients with prolonged urinary catheterization and in nosocomial settings. Infection with *Candida* may be seen in preterm infants, immunocompromised children and following prolonged antibiotic therapy.

PATHOGENESIS

In the neonatal period, renal parenchymal infection usually occurs by hematogenous spread. Ascending infection from the urethra to bladder and the kidneys is common in older children. Direct extension of infection can occur in the presence of fistulas from vagina or intestines to the urinary tract. Irrational antibiotic therapy may lead to fecal recolonization with virulent bacteria thereby predisposing to bacteriuria by disrupting the normal periurethral flora.

CLINICAL FEATURES

The symptoms of UTI in young children are nonspecific and require a high index of suspicion. In neonates, UTI may present with fever, irritability, poor feeding, vomiting, lethargy, jaundice and symptoms of systemic sepsis. Sometimes the child may present with recurrent fever, diarrhea, vomiting, abdominal pain and poor weight gain. Urinary symptoms such as burning, urgency, frequency, flank pain, turbid urine, intermittent voiding dysfunction and a recent onset of enuresis are seen in older children. About 5% of febrile children below 2 years without focus have UTI. It is difficult to predict based on symptoms whether a child has localized cystitis or pyelonephritis. A febrile UTI in young children should be considered as pyelonephritis.

DIAGNOSIS

Urinalysis is helpful in making a presumptive diagnosis of UTI and facilitates initiation of empirical treatment. However, confirmation of the diagnosis on urine culture is mandatory.

Collection of Urine

The specimen for urine culture should be obtained carefully to prevent contamination by commensal flora especially in females. A clean-catch specimen is most widely used in toilet-trained older children. The initial urinary stream washes away distal urethral organisms and should be discarded. In girls, parents should be instructed to part the labia while passing urine. Cleaning of the vulva in prepubescent girls or the meatus in boys is not necessary. Early morning urine samples harbor greater bacterial counts but are less amenable to outpatient practice.

In neonates and infants particularly girls, the best technique for obtaining an uncontaminated specimen is suprapubic aspiration from the bladder. It can be performed safely using a 21-gauge needle, 1–2 cm above the pubic symphysis. Occasionally parents may succeed in collecting a clean-catch sample in a male infant. Urine specimen can also be collected by temporary transurethral catheterization. Bag specimens have unacceptably high contamination rate, even with thorough cleaning of the prepuce or the perineum and are not recommended. A sterile culture from bag specimen is helpful in ruling out UTI. Use of diapers or absorptive pads for collecting urine for culture is not recommended.

In children with indwelling catheters, urine can be aspirated from the catheter using a sterile needle and syringe. Bacteria multiply in the bags and specimen obtained from this site is unsuitable. Obtaining appropriate urine specimen is difficult in patients with ureterostomy or vesicostomy. Catheterization of the stoma under asepsis is recommended and the culture result should be interpreted as any catheter specimen.

The sample should be transported to the laboratory as early as possible. If delay of more than 2 hours is anticipated, the specimen can be stored in a refrigerator at 4ºC for up to 72 hours before plating. This would preserve the white cell count and prevent growth of contaminating bacteria.

Urinalysis

The gold standard for diagnosis of UTI is urine culture. However, a major drawback of urine culture is the time-delay between collection of the specimen and identification of bacterial growth. Urinalysis is a useful screening test and facilitates initiation of therapy in patients with strong suspicion of UTI; however, it cannot be used as a substitute for urine culture. The sensitivity and specificity of various components of urinalysis and newer tests for diagnosing UTI is presented in **Table 1**.

Leukocyturia Presence of greater than 5 white cells/high-power field in a centrifuged urine sample or more than 10 white cells/mm in uncentrifuged urine is found in 80–90% of patients with symptomatic UTI. While leukocyturia may occur in several conditions resulting in inflammation in and around the urinary tract, its absence does not exclude UTI. White cell casts are highly suggestive of acute pyelonephritis. Leukocytes may lyse rapidly if urine microscopy is delayed.

Nitrate reductase It is based on reduction of nitrate to nitrite by nitrate reductase enzyme present in most coliforms. The sensitivity of nitrite test is low in infants who void frequently and have short bladder incubation time. It is also less reliable in young boys in

Table 1 Urinalysis and screening tests for diagnosis of urinary infection

Test	Sensitivity (%)	Specificity (%)
Leukocyte esterase	83	78
Nitrite	53	98
Leukocyte esterase and nitrite	72	96
Leukocyturia	73	81
Bacteria	81	83
Gram stain, any organism	93	95
Catalase	86	75
Lactoferrin	93	89
Bioluminescence	96	70
Turbidimetry	94	55

whom the preputial bacteria may reduce nitrite and give a false-positive result.

Leukocyte esterase A chloroacetate stain reacts with the enzyme leukocyte esterase found in neutrophil granules. Detection of leukocyturia by this test is reasonably sensitive but less specific for UTI. It is more accurate than microscopy because enzyme activity is still retained when white cells have disintegrated. Combination of leukocyte esterase and nitrite dipstick test is highly sensitive and specific for diagnosing UTI.

Detection of bacteriuria Microscopy of uncentrifuged, unstained urine will detect more than 10^4 bacteria/mL of urine. The presence of a single bacterium in a centrifuged or a Gram stained fresh urine specimen has a high sensitivity and specificity for predicting a positive urine culture. However, these methods are labor intensive.

Urine Culture

On culture, the bacterial count is important to differentiate true infection from contamination by periurethral flora. The cut-off figures for significant bacteriuria vary with the method of urine collection **(Table 2)**. Lower bacterial counts may be sufficient to diagnose UTI in children with urinary frequency and in newborns. A urine culture should be repeated in case of mixed growth suggestive of contamination.

Other investigations in patients with UTI include a blood urea, creatinine and leukocyte count. Nonspecific markers of inflammation such as leukocytosis, raised C-reactive protein do not provide confirmatory evidence of pyelonephritis. Photopenic areas on ^{99}Tc-dimercaptosuccinic acid (DMSA) scan indicate inflammation in the renal parenchyma and suggest pyelonephritis. However, detection of acute pyelonephritis by DMSA scan does not change the subsequent management and its routine use in clinical practice is not recommended.

MANAGEMENT

The aim of management of UTI is to prevent renal scarring and its subsequent complications. Younger age and delay in treatment of

Table 2 Method of urine sample collection and diagnosis of urinary infections

Method	Colony forming units per mL
Clean void	$> 10^5$
Transurethral catheterization	$> 10^4$
Suprapubic aspiration	Any
Bag specimen	Not recommended

Note: Lower counts may be acceptable in infants.

UTI are significant risk factors for renal scarring. Differentiation of acute pyelonephritis from cystitis in a child with UTI is difficult. Infants and sick children with suspected UTI should be treated promptly after obtaining urine culture. The choice of antibiotic should be guided by the most likely organism and its local susceptibility pattern. Although community-specific resistance rates among common urinary pathogens may not be readily available, accumulating data suggest that there is a trend towards increasing resistance to commonly used antimicrobial agents for treatment of UTI such as trimethoprim-sulfamethoxazole. Clinically UTI can be classified as complicated or uncomplicated.

Severe or Complicated UTI

The presence of fever greater than 39°C, marked toxicity, persistent vomiting, dehydration and renal angle tenderness suggests complicated UTI. Children less than 3 months of age and those with complicated UTI should be hospitalized and treated with parenteral antibiotics. A third-generation cephalosporin (cefotaxime or ceftriaxone) is preferred **(Table 3)**. Usually a single antimicrobial should be used in community-acquired infections and combinations should be reserved for critical cases. Oral cefixime is as efficacious as parenteral therapy in children with suspected acute pyelonephritis. Intravenous therapy with single daily dose of aminoglycoside has also been found to be safe and effective.

Intravenous therapy is given for the first 2–3 days. Once the result of antimicrobial sensitivity is available, treatment may be modified accordingly. When the clinical condition improves and the child is accepting by mouth, oral antibiotics may be started. Majority of febrile children with UTI have evidence of pyelonephritis, hence febrile urinary infections in young children should be treated for 10–14 days.

Uncomplicated UTI

Children more than 3–6 months of age, who are accepting by mouth and not toxic, may be treated with oral antibiotics **(Table 3)**. For uncomplicated UTI in otherwise healthy children with predominant lower tract symptoms, a 3- to 5-day course of therapy has been found to as efficacious as 7- to 10-day therapy.

Resolution of fever is expected by 48–72 hours with adequate therapy. Even under effective therapy, proven with repeat urine cultures, fever may persist for up to 3 days. Failure to respond to therapy may be due to presence of resistant pathogens, complicating factors, or noncompliance. Ultrasonography should be performed early if the expected clinical response is not observed. Routinely a urine culture to document response to therapy is not necessary and should be repeated only if the patient fails to respond to the therapy.

Genitourinary Imaging after UTI

The aim of imaging studies is to identify urologic anomalies that predispose a child to pyelonephritis and to detect evidence of renal scarring. The studies recommended are renal ultrasonography, either a radiocontrast voiding cystourethrography (VCUG) or direct radionuclide cystography (DRCG), and DMSA scan.

Renal Ultrasonography

Renal ultrasonography has completely replaced intravenous pyelography for assessing the gross anatomy of the urinary tract and it is routinely performed after the diagnosis of first UTI. It is a noninvasive test that can demonstrate the size the shape of the kidneys such as solitary or dysplastic kidney, horseshoe kidney and the presence of ureterocele. It is reliable for diagnosing urinary tract obstruction, which may be present in children with first UTI. Ultrasound (US) is not sensitive enough to detect presence of

Table 3 Antibiotics for treatment and prophylaxis of urinary tract infections (UTIs)

	Drug	Dose (mg/kg/day)	Duration
Uncomplicated UTI or cystitis	Oral Amoxicillin or Amoxicillin/clavulanic acid	30–40 in 3 divided doses	7 days
	Cephalexin	30–50 in 3 divided doses	
	Cefadroxil	30–40 in 2 divided doses	
	Cefixime	10 in 2 divided doses	
	Ciprofloxacin	10–20 in 2 divided doses	
Complicated UTI or pyelonephritis	*Parenteral*		10–14 days
	Gentamicin	5 in single dose	
	Amikacin	15 in single dose	
	Cefotaxime	100 in 3 divided doses	
	Ceftriaxone	75–100 in 1–2 divided doses	
Prophylaxis	*Single oral dose*		
	Cotrimoxazole	1–2 of trimethoprim	
	Nitrofurantoin	1–2	
	Nalidixic acid	15–20	
	Cephalexin	10	
	Cefadroxil	3–5	
	Cefaclor	5–10	
	Cefixime	2	

hydronephrosis or hydroureter secondary to VUR because of the dynamic nature of reflux. It is also poorly sensitive test for acute pyelonephritis and renal scarring.

Cystography

All forms of cystography require catheterization and are invasive with potential risk of UTI. Among all these tests, micturating cystourethrography (MCU) provides more information at the cost of higher radiation.

Micturating Cystourethrography

Micturating cystourethrography is the gold standard for diagnosing VUR. In MCU, bladder is filled with a radiocontrast agent by transurethral catheterization under fluoroscopic guidance and films taken during voiding **(Fig. 1)**. MCU permits grading of VUR defines urethral and bladder anatomy and function. The sensitivity of MCU can be increased by cyclic procedures, i.e., filling the bladder and having the child void two or more times. However, cyclic VCUG involves unacceptably high radiation burden.

Radionuclide Cystography

Direct radionuclide cystourethrography is an alternative for diagnosis and evaluation of VUR **(Fig. 2)**. It has a higher detection rate than MCU at a lower radiation exposure. The setbacks of DRCG are poor anatomical resolution, lack of urethral visualization, restricted grading capability. It is useful for follow-up of VUR because of minimal radiation.

Echo-enhanced cystosonography (EECS) offers a nonionizing method for evaluation of VUR. The procedure requires intravesical administration of an echo-enhancing agent (air-filled microbubbles) through transurethral catheterization. Its use is limited in clinical practice due to its drawbacks.

^{99}Tc-Dimercaptosuccinic Acid Scintigraphy

Renal cortical imaging with DMSA is sensitive and specific for the diagnosis of acute pyelonephritis. It is characterized by decreased radiotracer uptake caused by cortical ischemia and tubular dysfunction during acute infection. It is the most reliable investigation for scarring and also assessing renal function **(Fig. 3)**. For renal scarring, a DMSA scan should be performed preferably after 4–6 months after infection.

Figure 1 Micturating cystourethrography showing marked dilatation of pelvicalyceal system and ureter on right side suggestive of grade V vesicoureteral reflux (VUR)
Figure 2 Direct radionuclide cystourethrography (DRCG) showing severe reflux on right side
Figure 3 Tc-dimercaptosuccinic acid scan showing irregular renal outline (arrows) suggestive of renal scarring in both kidneys

Recommended Protocols for Evaluation after UTI

All children with UTI should be evaluated to identify those with an underlying urinary tract anomaly. However, UTI is so common that many children with no urinary tract abnormality would be subjected to investigations without benefit. Thus a *high-risk* approach should be followed. The recommendations for imaging following UTI are based on the assumption that early detection of urologic abnormalities especially VUR will lead to improved outcomes. **Table 4** outlines the protocols recommended by the Indian Society of Pediatric Nephrology (ISPN), American Academy of Pediatrics (AAP) and Royal College of Physicians (RCP). Only a few well-designed studies have tested the value of these imaging protocols. The opportunities for prevention of renal damage are most in young children. The ISPN recommends a renal US, MCU and DMSA scan in all children below the age of 1 year. A DMSA scan and renal US are recommended between ages 1 and 5 years. This recommendation is based on the fact that in majority an abnormal DMSA scan provides a clue to the underlying VUR. It is presumed that most vulnerable children would have already developed scars in infancy. Studies in infants have shown that the DMSA scans were abnormal with dilating VUR only.

By pursuing this policy, the number of MCU in this age group is restricted.

Milder reflux that may be missed by this approach, is assumed to not to be contributing to renal scarring. Further imaging with MCU is done if the DMSA scan or US shows abnormal findings. Only renal US is necessary above 5 years of age.

Routine renal US in all children with first UTI is justified in our country where prenatal US is not universal as in developed countries. Children with more than one episode of UTI, irrespective of age, should be evaluated with renal US, DMSA scan and MCU.

RECURRENT UTI

Recurrence after the first UTI is observed in 30–50% of children. Of these a majority occurs within 3 months of the initial episode.

E. coli is the most common organism causing these infections. There is greater incidence of infection by *Proteus, Klebsiella* and *Enterobacter* species in children with recurrent UTI. Recurrent UTIs are more common in infants and are usually caused by previously isolated organism rather than reinfection by new organism. Various predisposing risk factors for recurrent UTI in children are presented in **Box 1**.

PREVENTION

Recurrent UTI may predispose to renal scarring. Prevention is important and antibacterial prophylaxis is indicated in children with recurrent UTI. Underlying risk factors need to be identified and corrected. Interventions that have been associated with a decrease in incidence of UTI include relief of constipation and voiding dysfunction. Currently available probiotics are not recommended to treat or prevent UTI.

Antibiotic Prophylaxis

Although the evidence of benefit of long-term low-dose antibiotic prophylaxis for prevention of UTI is not very strong, it is the most widely used strategy to prevent UTI in clinical practice. Antibiotic prophylaxis is recommended in (1) children with VUR; and (2) those with recurrent febrile UTI even if the urinary tract is normal. Medications used for prophylaxis **(Table 3)** are usually given as single bedtime dose.

The ideal antibiotic for prophylaxis should have a broad spectrum of action and achieve a high urinary concentration with minimal alteration of the bowel flora. The precise mechanism of action of low-dose antibiotic prophylaxis is not known. Nitrofurantoin and cotrimoxazole are the most commonly used drug for long-term prophylaxis. UTI during antibiotic prophylaxis (breakthrough UTI) may result from noncompliance or development of bacterial resistance, mainly occurring with trimethoprim. Nitrofurantoin is associated with nausea and vomiting that may result in discontinuation of therapy in a significant proportion of patients. Cephalexin is preferred in young infants and those with deficiency of the enzyme, glucose-6-phosphate-dehydrogenase. Amoxicillin, nalidixic acid and other quinolones should be avoided for prophylaxis because intestinal colonization with *E. coli* resistant to these agents occurs rapidly. Reinfection of the urinary tract with these resistant bacteria may then occur. Low-dose cefixime is also effective and safe in the prophylaxis of recurrent UTI.

ASYMPTOMATIC BACTERIURIA

It is defined as significant bacteriuria in the absence of symptoms of UTI. The frequency of asymptomatic bacteriuria is about

---

BOX 1 Risk factors for recurrent urinary tract infection (UTI)

- Female sex
- Obstructive uropathy
- Severe (grade III–V) vesicoureteric reflux
- Repeated pyelonephritis
- Voiding dysfunction
- Constipation
- Repeated catheterization in neurogenic bladder.

Table 4 Imaging protocols following first urinary tract infection (UTI)

	US	*VCUG*	*DMSA scan*
Indian Society of Pediatric Nephrology	All	< 1 year	< 5 years
*American Academy of Pediatrics	< 2 years	< 2 years	Not recommended
Royal College of Physicians London	All	< 1 year	1–7 years

*Recommendations for < 2 years old only.
Note: Perform all [ultrasonography (US), voiding cystourethrography (VCUG) and Tc-dimercaptosuccinic acid (DMSA)] if any of the above test is abnormal.

1% in girls and 0.05% in boys. The organisms isolated in most cases are usually *E. coli* that of low virulence. The condition is benign and does not cause renal injury. It has been shown to remit spontaneously with time. However, eradication of these nonpathogenic organisms may be followed by symptomatic infection with more virulent strains. Use of antibiotics to treat asymptomatic bacteriuria or antibiotic prophylaxis is therefore not indicated even in the presence of VUR.

VESICOURETERIC REFLUX

Vesicoureteric reflux is a retrograde flow of urine from the bladder into the ureter. It is seen in 30–50% children and 40–50% of infants with UTI. It may predispose to renal parenchymal infection by allowing ascent of bacteria from bladder to the upper urinary tract. VUR is categorized as primary or secondary.

ETIOLOGY

Primary VUR is attributed to an abnormally short intravesical segment of ureter which does not allow its constriction at the ureterovesical junction by contracting detrusors, resulting in reflux. Secondary VUR is due to increased bladder pressures such as those seen with urethral valves and neurogenic bladder.

PATHOGENESIS

There is a strong inheritance pattern for primary VUR. The chance of a sibling of a child with VUR having reflux is about 25%. If one of the parents had a VUR, there is 25–50% increased risk of reflux in offspring. The reflux is usually of low grade and an increased risk of UTI has not been shown in these patients. Age of sibling below 2 years, twin relationship and absence of dysfunctional voiding in index patient have been identified as risk factors for detecting reflux in siblings. A genetic basis for VUR seems evident from the familial clustering of cases in predominantly autosomal dominant, but also in autosomal recessive, X-linked and polygenic patterns. VUR may be associated with developmental malformations of other organs such as eye, ear and face and is termed as syndromic VUR. Several genes have been identified for this form of VUR. Some of the candidate genes found to be associated with primary nonsyndromic VUR include *ROBO2*, *SOX17*, *UPK3A* and *AGTR2*; however, the association is inconsistent suggesting genetic heterogeneity underlying this disorder.

Reflux Nephropathy

Primary VUR is associated with renal scarring which is termed as reflux nephropathy. Experiments have shown that reflux of infected urine can cause renal parenchymal inflammation and scarring. However, severely scarred or shrunken kidney associated with VUR is now believed to be renal dysplasia secondary to fetal reflux and is not secondary to UTI. Children with renal dysplasia mostly have severe grade of VUR; some of whom have never had UTI.

CLINICAL FEATURES

Vesicoureteric reflux is most commonly diagnosed after evaluation for a UTI. However, it may also be detected in asymptomatic children with antenatally diagnosed hydronephrosis and screening of siblings of patients with VUR. It is also diagnosed during evaluation for hypertension, small contracted kidney or chronic kidney disease. While it is more commonly reported in girls presenting with UTI in the West, boys are more often affected in Asia. Presentation with antenatal hydronephrosis is seen common in boys and is associated with severe grades of reflux and scarring.

DIAGNOSIS

The gold standard for diagnosis of VUR is MCU. The approach to diagnosis of VUR in a child following UTI is discussed above. The severity of VUR is graded using the International Study Classification from grade I–V based on the appearance of the urinary tract on contrast MCU as shown in **Figure 4**. Renal US has 50–60% sensitivity for diagnosing VUR. Routine screening of siblings of patients with reflux using VCUG is not done universally. Siblings of children with VUR may be screened using US. The benefit of screening for VUR in asymptomatic siblings is unclear.

The presence of moderate to severe reflux is associated with risk for acute pyelonephritis and reflux nephropathy. Severely scarred can be diagnosed on ultrasonography. Intravenous pyelography is low sensitivity for diagnosing renal scarring and is not indicated for diagnosing reflux nephropathy. DMSA scan is the most sensitive test for detecting small scars. However, since result of DMSA scan does not influence the management of VUR and it has radiation exposure, regular scanning is discouraged.

Bladder-Bowel Dysfunction and VUR

There is increasing evidence that bladder and bowel dysfunction may be found in a significant proportion of children with VUR. Symptoms of unstable bladder include frequency, urgency, incontinence and holding maneuvers. Patients with uncoordinated bladder show urgency, hesitancy and, diurnal and nocturnal incontinence. About one-third of children with bladder dysfunction may be asymptomatic.

All patients with VUR should be assessed for bladder and bowel dysfunction. A detailed history including voiding pattern and bowel habits is important. Constipation is a proven risk factor for recurrent UTI. Examination of lower back should be done for spinal dysraphism. Findings on MCU and US may suggest bladder

| Grade I | Grade II | Grade III | Grade IV | Grade V |
Figure 4 International reflux study grading of vesicoureteral reflux (VUR). *Grade I:* Reflux into the ureter only; *Grade II:* Reflux into nondilated pelvicalyceal system; *Grade III:* Dilatation of ureters and pelvicalyceal sytem; *Grade IV:* Extensive dilation with blunting of calyces with intact papillary impression and tortuosity of ureter; *Grade V:* Massive dilatation of collecting system with clubbing of calyces and loss of papillary impressions and tortuosity of ureter

Table 5 Management and follow-up of primary vesicoureteral reflux (VUR)

VUR grade	Management	Follow-up
I–II	Antibiotic prophylaxis until 1-year old	Observation Restart prophylaxis if breakthrough febrile UTI
III–V	*< 5 years of age:* Antibiotic prophylaxis *> 5 years of age:* Prophylaxis continued if bowel bladder dysfunction	Consider surgery if breakthrough febrile UTI; alternatively, consider a change of antibiotic

dysfunction. Urodynamic study is necessary if bladder dysfunction is clinically suspected.

MANAGEMENT

Traditional treatment of VUR has been surgical reimplantation until it was discovered that children with VUR may do well with low-dose antibiotic prophylaxis. There is strong evidence suggesting that the incidence of recurrent UTI, renal growth and progression or appearance of new scars among patients treated with prolonged antibiotic prophylaxis versus surgical reimplantation is similar. Medical management is therefore regarded as effective as surgery with no clear benefits of surgery over it. The guidelines of ISPN are summarized in **Table 5**.

Antibiotic Prophylaxis

Antibacterial prophylaxis while awaiting spontaneous resolution of VUR is the cornerstone of treatment. This treatment usually suffices for most patients and has been found to be as effective as surgical reimplantation. Surveillance urine cultures, in asymptomatic patients, are not necessary. Treatment of asymptomatic bacteriuria even in patients with VUR is not required and may be harmful. However, urine cultures should promptly be obtained in presence of symptoms. Symptomatic UTI in children with VUR should be treated promptly. Parents should be educated to maintain a high index of suspicion for subsequent UTI.

Patients should be monitored for physical growth and hypertension. Compliance with antibiotic prophylaxis should be ensured on follow-up visits. Investigations include urinalysis, yearly estimation of blood urea and creatinine. Yearly US examination is done to monitor the renal growth. DRCG scan may be done during follow-up to assess resolution in high-grade reflux. A DMSA scan during follow-up may be of prognostic significance. The optimum duration of prophylaxis is not clear. It can also be stopped in a child with low-grade reflux, after 5 years of age in the absence of breakthrough UTI and bladder-bowel dysfunction.

Surgical Reimplantation

Currently the indications of surgery are limited. Recurrences of UTI (breakthrough infections), formation of new scars and decreased renal function may no longer be considered as indications for surgical repair. Surgical correction may be considered in patients with: (1) persistent severe reflux; (2) noncompliance with medical management; (3) parental preference for surgery over prolonged antibiotic prophylaxis; and (4) deterioration of function during antibiotic prophylaxis in a previously normal kidney. Urodynamic evaluation is preferable prior to surgical repair. Surgery is also necessary in patients where VUR is secondary to obstruction (e.g., posterior urethral valves), ureteral duplications or paraureteric diverticuli.

Endoscopic Injection

Endoscopic injection of implant material dextranomer/hyaluronic acid polymer (Deflux), in the submucosal ureteric tunnel, has been advocated for correction of reflux. It has been proposed as an alternative to antibiotic prophylaxis or surgery for persistent VUR. However, the success rate is variable, sometimes requiring multiple injections depending upon the expertise of the urologist.

Further significant proportion of patients may develop recurrence of VUR on long follow-up.

PROGNOSIS

Majority of primary VUR including severe grades resolve completely or become less severe as the child grows. The chances of resolution are highest with low grades of reflux. Untreated bladder-bowel dysfunction is associated with persistence of reflux.

Long-term studies have shown that small scars associated with primary VUR are unlikely to cause hypertension and renal failure. Children with VUR and renal dysplasia are at risk of developing hypertension and end-stage renal failure in later life.

IN A NUTSHELL

1. The symptoms of UTI may be nonspecific and require high index of suspicion.
2. Urinary tract infection should be diagnosed and treated promptly to prevent renal scarring.
3. Urinalysis is helpful in making a presumptive diagnosis of UTI but is not a substitute for urine culture; combination of leukocyte esterase and nitrite reductase is sensitive and specific for diagnosing UTI.
4. Majority of febrile children with UTI have acute pyelonephritis which need not be documented by DMSA scan in clinical practice.
5. Febrile UTI in young children should be treated for at least 7–14 days; uncomplicated lower tract infection in older children may be treated for 3–5 days.
6. Almost one-third to half of all patients with UTI has VUR; all children with first UTI should be evaluated using a high-risk approach.
7. Voiding dysfunction and constipation are important causes of recurrent UTI.
8. Asymptomatic bacteriuria is not harmful and should not be treated.
9. The cornerstone of therapy for primary VUR is antibiotic prophylaxis.
10. While secondary VUR should be treated surgically, indications of surgery for primary VUR are limited.

Chapter 41.20
Dysfunctional Voiding
Madhuri Kanitkar, Suprita Kalra

The symptoms of bedwetting, incontinence and recurrent urinary tract infections with bladder related symptoms such as urgency, frequency and straining during micturition might result from an underlying anatomical anomaly or a neurological disorder affecting the lower urinary tract, which at times may be occult. However, the symptoms may occur in the absence of either, in which case it is defined as *dysfunctional voiding.* These disorders have a multifactorial etiology. The prevalence of daytime urinary incontinence is around 7–8%. Genetic basis has been reported for some conditions, e.g., urofacial (Ochoa) syndrome, with loss of function mutation in the heparanase 2 gene presenting with a non-neurogenic neurogenic bladder and typical facial grimace when smiling.

CLASSIFICATION OF VOIDING DISORDERS

The International Children's Continence Society (ICCS) in 2006 recommended the use of standard nomenclature for voiding disorders in children **(Table 1)**.

ANATOMY AND INNERVATION OF URINARY BLADDER

The urinary bladder consists of a balloon-shaped reservoir with an outlet at the neck which continues into the urethra. The bladder outlet has two sphincters: (1) the internal sphincter constituted by the detrusor muscle and elastic fibers and (2) the external sphincter constituted by the pelvic floor skeletal muscle. The two important functions of the urinary bladder of (1) storage and (2) evacuation are controlled by a complex neuromyogenic system. The parasympathetic system is responsible for bladder emptying by inducing contraction of the detrusor and relaxation of the internal sphincter. The sympathetic system is responsible for relaxation of the bladder and contraction of the sphincter, ensuring continence during the filling phase. The somatic efferent nerve innervates the external sphincter. The sensation of bladder distention is transmitted by the afferent myelinated fibers. The central pontine micturition center coordinates detrusor contraction and sphincter relaxation that results in voiding. Cortical control is through the anterior cingulate gyrus. Voiding is initiated in the cerebral cortex through relaxation of the external sphincter, followed by inhibition of sympathetic and increase in parasympathetic activity resulting in detrusor contraction with relaxation of the internal sphincter.

Table 1 Definitions for lower urinary tract symptoms

Terminology	Definition
Decreased daytime voiding frequency	Three or fewer voids per day
Increased daytime voiding frequency	Eight or more voids per day
Polyuria	24 hours urine output > 2 L/m^2 body surface area (BSA)
Expected bladder capacity	Age related expected maximum voided volume (MVV), as determined by the formulae: Children > 2 years: [30 + (age in year × 30)] mL; Children < 2 years: [wt. in kg × 7] mL
Nocturnal polyuria	Overproduction of urine at night, defined as nocturnal urine output > 130% of bladder capacity for age
Incontinence	Uncontrollable leakage of urine
Continuous incontinence	Continuous leakage of urine
Intermittent incontinence	Leakage of urine in discrete portions during the day and or night
Urge incontinence	Incontinence when experiencing urgency
Voiding postponement	Incontinence in the presence of habitual holding maneuvers
Enuresis	Incontinence of urine while sleeping
Monosymptomatic enuresis	Enuresis without other lower urinary tract symptoms
Nonmonosymptomatic enuresis	Enuresis with lower urinary tract symptoms such as daytime incontinence, urgency and holding maneuvers
Primary enuresis	Enuresis in a child who is previously dry for < 6 months
Secondary enuresis	Enuresis in a child who is previously dry for > 6 months
Overactive bladder	Condition in patients experiencing urgency symptoms
Underactive bladder	Low voiding frequency; need to increase intra-abdominal pressure to void (lazy bladder)
Dysfunctional voiding	Habitual contraction of the urethral sphincter during voiding, as observed by uroflow measurements
Maximum voided volume	Largest voided volume documented in a bladder diary; replaces the term functional bladder capacity. MVV < 65% of expected bladder capacity suggests small capacity; MVV > 150% of expected bladder capacity indicates large capacity
Detrusor underactivity	Cystometric observation of a contraction of decreased strength and/or duration, resulting in prolonged bladder emptying and/or a failure to achieve complete bladder emptying
Detrusor overactivity	Cystometric observation of involuntary detrusor contractions during the filling phase
Residual urine	Urine left in the bladder after voiding. Residual urine in excess of 20 mL or > 10% of expected bladder capacity indicates incomplete bladder emptying

MATURATION OF BLADDER CONTROL

At birth micturition is spontaneous as a spinal cord reflex. Between 1 year and 2 years of age, the bladder capacity increases along with neural maturation of the cortical center. The sensation of bladder filling is present but voiding occurs still as a reflex. During 3–4 years of age micturition can be delayed by voluntary use of the external sphincter, resulting in daytime continence. By 5 years, the child is dry by night and true cortical inhibitory control is achieved. The final step in maturation is when a child is able to void at will even if the bladder is not full. Majority of children are dry during the day by 2–3 years and at night by 3–4 years. Fecal continence precedes urinary continence.

VOIDING DISORDERS

These are defined as functional, abnormal patterns of micturition in the presence of intact bladder innervation and without any congenital or anatomical anomaly of the lower urinary tract. These may be classified as:

Filling phase disorder An overactive bladder with or without incontinence.

Evacuation phase disorder Dysfunctional voiding.

Over a period of time, a dyssynergic bladder that contracts against a closed external or internal sphincter may result in a low pressure hypotonic underactive bladder, leading to overflow incontinence. Severe bladder sphincter dyssynergia is noted in the Hinman syndrome where the urinary bladder is trabeculated, develops a high pressure state with bilateral vesicoureteric reflux and a large postvoid residue akin to neurogenic bladder without an obvious underlying neurological abnormality. The condition requires early diagnosis and treatment as high retrograde pressures invariably lead to renal failure.

Bowel Bladder Dysfunction

This term describes the subset of children with both bladder and bowel voiding difficulties. Many children with bladder problems may reduce fluid intake to minimize wetting, and powerful pelvic floor muscle contractions lead to postponement of defecation and constipation. This further worsens bladder functioning. On the other hand, children with functional constipation may have an increased risk for voiding disorders and urinary infections. In severe situations, children present with fecal incontinence or encopresis.

CLINICAL FEATURES

Primary monosymptomatic nocturnal enuresis presenting with bedwetting needs to be differentiated from the more complex voiding disorders. An overactive bladder presents with increased frequency of voiding, urgency of micturition and holding maneuvers with or without dampness of the underpants due to urge incontinence. These holding maneuvers are also seen in children who habitually postpone voiding; symptoms are aggravated in the evening when the pelvic floor muscles are fatigued. The child with dysfunctional voiding may present with recurrent urinary tract infections, straining to void and lower abdominal pain. Constipation, in almost two-thirds of children with voiding disorders, further worsens bladder functioning. Psychological comorbidity or behavioral disturbances are often noted.

EVALUATION

The first step is to differentiate monosymptomatic primary nocturnal enuresis from a voiding disorder. Clinical examination is required to exclude a neurological or an anatomical basis. This includes examination of back to rule out spinal and sacral anomalies and the abdomen for palpable bladder or kidneys. The lower limbs are assessed for tone, power and sensations, and perineum and external genitalia examined for ectopic ureters, epispadias in boys and vaginal pooling or labial adhesions in girls. A clinical management tool aids history taking **(Box 1)**.

INVESTIGATIONS

A voiding diary is an important component of evaluation that helps ascertain the nature of the problem. It is recommended that the diary be maintained over a minimum of 2–3 days for accuracy, preferably during holidays. Bedwetting diary should be maintained for seven consecutive nights to assess the severity of the problem, detect the presence of nocturnal polyuria and differentiate voiding disorder from monosymptomatic enuresis. **Table 2** lists investigations that are indicated for a child with a voiding disorder. Detailed history, using the clinical management tool, voiding diary and ultrasonography of the abdomen is sufficient in most children.

Detrusor overactivity presents as an overactive bladder with nocturnal enuresis, daytime symptoms, holding maneuvers, small frequent voiding pattern, and a small capacity bladder with insignificant postvoid residue. Dysfunctional voiding due to a bladder sphincter dyssynergia is associated with straining, large capacity bladder and significant postvoid residue. Invasive urodynamic studies are difficult in young children, and not routinely required. Indications for the investigation are: (1) suspected neurologic abnormality; (2) urinary and fecal incontinence; (3) trabeculations of bladder and funneling of sphincter on micturating cystourethrography; (4) failure to respond to therapy for voiding disorder diagnosed using noninvasive assessment.

TREATMENT

The treatment of monosymptomatic nocturnal enuresis is motivation with rewards for dry nights and behavioral therapy

---

BOX 1 Checklist of clinical management tool

Refer for evaluation if any of the following symptom is present in a child with enuresis
- Symptoms suggestive for underlying bladder dysfunction
  - Leakages of urine during the day
    - Drops of urine in the under pants
    - Very wet under pants
  - Intermittent or continuous leakage every day?
  - History of daytime incontinence after 3½ years of age
  - Urinary frequency (number of voids during the day; abnormal if < 3 or > 8)
  - Sudden and urgent need to urinate
  - Holding maneuvers observed
  - Needs to push in order to urinate
  - Interrupted urinary stream, or several voids, one after another
- History of urinary tract infection
- Illness and/or malformation
  - Kidneys and/or urinary tract
  - Spinal cord
- *Bowel movements:* Presence or history of either of the following
  - Constipation
  - Traces of feces in the underpants
- *Psychological, behavioral or psychiatric problems:*
  - Evidence of attention deficit hyperactivity syndrome or autism
  - History of motor and/or learning disabilities or delayed development
- *Drinking habits:*
  - Quantity and type of fluid intake
  - Drinks more than one glass during the evening
  - Drinks during the night.

Table 2 Investigations for children with dysfunctional voiding

Investigation	Abnormality detected	Inference
Urinalysis	Glucosuria	Consider diabetes mellitus
	Proteinuria (++ or more)	Consider chronic kidney disease
	> 10 leukocytes per high-power field	Consider urinary infection
Ultrasonography of kidneys and urinary bladder	Bladder wall thickness > 2 mm	Neurogenic bladder, bladder outlet obstruction
	Significant postvoid residue	Incomplete voiding, vesicoureteric reflux, bladder outlet obstruction
	Bladder wall irregularity	Recurrent urinary infection or cystitis
	Hydroureteronephrosis	Obstructive uropathy, vesicoureteric reflux
	Small shrunken kidney(s)	Chronic kidney disease
	Calculi, nephrocalcinosis	Obstructive uropathy
Micturating cystourethrography	Bladder wall irregularity; elongation of bladder shape	Overactive bladder
	Filling of the posterior urethra; spinning top configuration of bladder	Dysfunctional voiding
Magnetic resonance imaging of lumbosacral spine	Tethered cord, diastematomyelia, spine trauma, tumors, degenerative disorders	Neurogenic bladder

using the alarm. Medications are useful in case of an overactive bladder. In children with a voiding disorder, the basis of treatment lies in the exclusion of a neurological cause, treatment of urinary tract infection and (re)-institution of a structured timely voiding pattern with good hydration and hygiene. Treatment of constipation is possible by simple measures like increasing fluid intake, increasing intake of dietary fiber and use of husk (*isabgol*) or lactulose. Nonabsorbable polyethylene glycol powder is easy to prepare and administer.

Overactive bladder is treated with an anticholinergic medication like oxybutynin starting at 2.5 mg to a maximum dose of 15–20 mg/day in three divided doses. Side effects like blurring of vision, headache and diarrhea may be less with tolterodine, at a dose of 1 mg twice daily for children aged 5–10 years. Newer medications like solifenacin, capsaicin and resiniferatoxin and intravesical injection of botulinum toxin are being evaluated to further reduce side effects.

Biofeedback therapy aids retraining children to develop relaxed voiding. Behavioral intervention comprising patient education, scheduled voiding regimen with gradual increasing intervals, urgency control strategies, self-monitoring, and positive reinforcement helps children learn to relax the pelvic floor muscles. Deep breathing exercises, using a relaxed posture and enough time to void while keeping the palms over the abdominal wall are useful. Explaining pelvic floor relaxation exercises to the child and mother with repeated reinforcement is required.

Combination of biofeedback and alpha-blockers like doxazosin (0.5–1 mg/day) has been found useful in patients with dysfunctional voiding. In children with severe dysfunctional voiding and large postvoid urine, clean intermittent catheterization is instituted. Surgical intervention for dysfunctional voiding is reserved for patients who have failed all medical interventions. For children who need bladder emptying but have difficulty in performing clean intermittent catheterization per urethra, an alternative route can be surgically created using the appendix as a conduit in the Mitrofanoff technique. For patients with severe detrusor instability and small capacity bladders, augmentation cystoplasty may be useful.

IN A NUTSHELL

1. Voiding disorders are functional, abnormal patterns of micturition in the presence of intact innervation and without any congenital or anatomical abnormality of the urinary bladder.
2. These are essentially either filling phase disorders with an overactive bladder or evacuation disorders with dysfunctional voiding.
3. Voiding disorders need to be suspected in children presenting with enuresis; history of daytime symptoms should be elicited.
4. Detailed history, clinical examination, voiding diary and abdominal ultrasonography are sufficient in most cases.
5. Treatment of constipation, medications for an overactive bladder and reinstitution of a regular voiding pattern are key components of management.

Chapter 41.21
Chronic Kidney Disease
Erica Winnicki, Lavjay Butani, Stephanie Nguyen

Chronic kidney disease (CKD) is often silent until the disease has progressed to a very advanced stage. Therefore, early diagnosis is important to slow the progression of disease and minimize its associated morbidity and mortality. The kidney disease outcomes quality initiative (KDOQI) by the national kidney foundation (NKF) in the United States has published sets of evidence-based guidelines related to the care of adult and pediatric patients with CKD. In conjunction with the NKF, an international working group, the Kidney Disease Improving Global Outcome (KDIGO) initiative, has contributed tremendously to develop similar guidelines at an international level with the aim of improving care for this high-risk population.

DEFINITIONS

Chronic kidney disease is defined as any abnormality of kidney structure or function present for more than 3 months and is classified based on glomerular filtration rate (GFR) **(Table 1)**. Structural or functional abnormalities include any one of the following: abnormalities related to kidney function on blood tests, urinary abnormalities, abnormalities on imaging studies of the kidney, or pathology on a kidney biopsy. This classification system cannot be applied to very young children, until 2 years old, since the body surface area adjusted GFR does not approach adult values until that time.

Measurements of GFR traditionally have been made by determining clearance of creatinine or other markers such as inulin or iothalamate. An alternative and more convenient approach is to estimate GFR (eGFR) using one of many calculations **(Table 2)**.

EPIDEMIOLOGY

The incidence and prevalence of CKD in children are not well established since disease registries focus on those who have end-stage renal disease (ESRD). The ESRD population represents a very small fraction of all those with CKD since children in early stages of CKD may be asymptomatic or have mild symptoms and therefore not seek care. The magnitude of CKD can be extrapolated using population-based studies, which estimate the prevalence of CKD stage 1–4 in adults to be 10.8%, approximately 50 times the prevalence of ESRD (0.2%).

The United States, New Zealand and Austria have high incidence of pediatric ESRD, reportedly 12.4–14.8/million people while Japan had the lowest at 4.3/million people. The incidence and prevalence of ESRD and CKD in children in India is unknown as there are no regional disease registries. Studies are primarily from referral centers; which suggest that most children present in more advanced stages, as many as one-half presenting in ESRD.

ETIOLOGY

The etiology of CKD in children is quite different compared to adults in whom diabetes and hypertension are the most common causes. The causes in children are more varied. There is a predominance of congenital anomalies of the kidney and urinary tract (CAKUT), especially in the younger children. With increasing age, glomerular diseases assume greater importance.

PROBLEMS AND MANAGEMENT

Children with CKD may present with signs and symptoms of the underlying disease that is causing renal injury, such as hematuria, edema or oliguria in the setting of glomerulonephritis, or urinary tract infections and enuresis in children with CAKUT. Many children with CAKUT are now identified prenatally, due to the practice of obtaining routine screening prenatal ultrasounds during pregnancy. However, CKD is often clinically silent. Patients with structural renal anomalies are often nonoliguric and might escape recognition.

Anemia

Anemia is common in all stages of CKD and nearly universal in patients with advanced stages. Findings from the CKiD study, a prospective cohort study in North America, determined that above a GFR of 43 mL/min/1.73 m^2, hemoglobin fell by 0.1 g/dL for every 5 mL/min/1.73 m^2 decrease in GFR. Below an eGFR of 43 mL/min/1.7 3m^2, the hemoglobin declined by 0.3 g/dL for every 5 mL/min/1.73 m^2 decline in GFR. Anemia is multifactorial in origin, though the primary cause is decreased erythropoietin production by peritubular fibroblasts of the renal cortex. Another contributor is iron deficiency, caused by nutritional deficiency, increased blood loss (platelet dysfunction, frequent phlebotomy or blood loss in the dialysis tubing) and poor iron absorption. Other causes of anemia include short erythrocyte survival, deficiencies of B12 or folate, bone marrow suppression from hyperparathyroidism and chronic inflammation.

The evaluation of anemia in children with CKD includes complete blood cell count with red cell indices, absolute reticulocyte count, serum ferritin, folate and B12, and transferrin saturation. Anemia of CKD is usually normochromic and normocytic with normal reticulocyte count. Treatment of anemia includes iron replacement as well as administration of erythropoietic stimulating agents, specifically intravenous (IV) or subcutaneous (SC) recombinant human erythropoietin or an analog of erythropoietin, darbepoetin, which has a longer half-life. Use of these agents has dramatically decreased the need for blood transfusions in patients with CKD. A target hemoglobin for adult patients with CKD of less than 11.5 g/dL is recommended; target hemoglobin for children is 11–12 g/dL.

Mineral and Bone Disorders

Disorders of calcium-phosphate homeostasis are common in children with CKD and lead to abnormalities of bone turnover

Table 1 Definition of chronic kidney disease in children

Category	GFR (mL/min/1.73 m^2)	Action plan
Stage 1	≥ 90	Identify, treat and slow progression of underlying condition
Stage 2	60–89	
Stage 3	30–59	Evaluate and treat complications of CKD
Stage 4	15–29	Prepare for kidney replacement therapy
Stage 5	< 15 or on dialysis	Kidney replacement therapy

Abbreviations: GFR, glomerular filtration rate; CKD, chronic kidney disease.

Table 2 Pediatric glomerular filtration rate (eGFR) estimating equations

Creatinine-based equation	eGFR, mL/min/1.73 m^2 = 41.3 x (height, m/serum creatinine, mg/dL)
Cystatin C-based equation	eGFR, mL/min/1.73 m^2 = 70 x (serum cystatin, mg/L)$^{-0.931}$

and poor linear growth. Factors that contribute to these disorders include decreased 1,25(OH) vitamin D_3 synthesis and decreased renal phosphate excretion. Normally, the kidney converts 25(OH) vitamin D_3 to its active form, 1,25(OH) vitamin D3 via 1α-hydroxylase. 1,25(OH) vitamin D_3 increases intestinal absorption of calcium. Early in CKD, fibroblast growth factor 23 (FGF23), a circulating peptide made in the osteoclasts with phosphaturic properties, is increased and suppresses 1α-hydroxylase expression. With progression of CKD, production of 1,25(OH) vitamin D_3 decreases resulting in hypocalcemia. Loss of GFR also leads to decrease in renal phosphorus excretion resulting in high levels. Hypocalcemia, hyperphosphatemia and decreased 1,25(OH) vitamin D_3 stimulate parathormone (PTH) secretion, which increases bone turnover resulting in renal osteodystrophy.

Management of metabolic bone disease in CKD includes dietary restriction of phosphorus, use of phosphate binders, and supplementation with vitamin D and calcium. In the setting of hyperphosphatemia, patients should be instructed to restrict dietary intake of phosphorus. However, dietary phosphorous restriction is a limited strategy as phosphorous is present in most high-quality protein foods and overzealous restriction can lead to protein malnutrition. As a result, phosphate binders given with meals to bind phosphorus in the food so as to increase its elimination via the gastrointestinal tract are often required. Calcium-based phosphate binders such as calcium carbonate are commonly used for both dietary calcium supplementation and for phosphate binding, but can cause hypercalcemia and vascular calcifications when used in excessively large amounts. Calcium-free binders such as sevelamer are an option when additional calcium is not desired. Patients deficient in inactive vitamin D should receive supplementation. Active analogs are used if secondary hyperparathyroidism persists after correction of inactive vitamin D deficiency; adjustment of therapy is guided by PTH target levels that vary based on CKD stage. Oversuppression of PTH is to be avoided as a low bone turnover state may result and lead to adynamic bone disease **(Table 3)**.

Growth Impairment

Growth impairment is a common complication of CKD, and is associated with increased morbidity, mortality and lower health-related quality of life. Growth impairment is multifactorial and is more severe with younger onset of CKD given that infancy and early childhood are periods of very rapid growth. Inadequate nutrition resulting from anorexia and nausea/emesis secondary to uremia contributes in large part to growth failure. Additionally, CKD is a state of growth hormone (GH) resistance, with normal or elevated GH levels but decreased receptors and impaired signaling. Bioavailability of insulin-like growth factor-I is also decreased.

Caloric intake should be optimized, through use of oral or enteral nutritional supplements. Electrolyte abnormalities, including hyponatremia, acidosis and derangement in calcium/phosphorus, may contribute to poor growth and should be corrected. If poor linear growth persists, recombinant human GH is administered subcutaneously at doses to overcome the resistance to GH and aid in attainment of a more normal adult height.

Hypertension

Hypertension, of multifactorial etiology, is extremely common in children with CKD. Contributors include activation of the renin-angiotensin-aldosterone system, sodium retention and fluid overload, hyperactivity of the sympathetic nervous system, and iatrogenic hypertension resulting from medications, such as corticosteroids which are often used in CKD. Treatment of hypertension is of paramount importance and is initiated when blood pressure is consistently above the 90th percentile for age, sex and height. The goal of therapy is to lower blood pressure consistently to 50–75th percentile unless there are signs or symptoms of hypotension.

Pharmacological therapy is guided by the underlying etiology of hypertension. Diuretics, along with salt and fluid restriction, are appropriate for those with fluid overload. Patients with CAKUT may actually have a salt wasting nephropathy, where diuretics are not appropriate. Angiotensin converting enzyme (ACE) inhibitors or angiotensin receptor blockers have renoprotective and antiproteinuric effects and are considered first-line agents when there is no contraindication to their use, with monitoring for decrease in GFR and hyperkalemia. Many patients require multiple pharmacologic agents for adequate blood pressure control.

Electrolyte Disorders

Metabolic acidosis and hyperkalemia are important electrolyte abnormalities in patients with CKD. Metabolic acidosis is one of the earliest electrolyte derangements that develops when the GFR falls below 50% of normal. Metabolic acidosis is secondary to decreased ammonia production, low titratable acid excretion and reduced bicarbonate reabsorption. Chronic acidosis is associated with bone demineralization and increased protein degradation. Acidosis is managed with bicarbonate supplementation to maintain a serum bicarbonate concentration greater than or equal to 22 mEq/L.

Hyperkalemia is a problem for patients with severe CKD since distal tubular secretion of potassium remains intact in early CKD. It may be seen earlier in patients with distal renal tubular resistance to aldosterone, such as patients with obstructive uropathy, in patients with sudden decrease in effective circulating volume or increase in potassium load, or following therapy with ACE inhibitors. Management includes dietary restriction of potassium, correction of acidosis and use of sodium polystyrene sulfonate (orally, rectally or mixed with meals) to increase its gastrointestinal elimination.

Table 3 The kidney disease outcomes quality initiative (KDOQI) guidelines: bone metabolism and disease in children with chronic kidney disease (CKD)

Stage	iPTH (pg/mL)	Calcium (mg/dL)	Phosphorus (mg/dL)	Alkaline phosphatase (IU/L)
2	Normal	Normal for age: 0–3 months: 8.8–11.3	Normal for age: 0–3 months: 4.8–7.4	Normal for age: 0–3 months: 100–300
3	35–70	1–5 year: 9.4–10.8 6–12 year: 9.4–10.3	1–5 year: 4.5–6.5 6–12 year: 3.6–5.8	1–5 year: 100–350 6–12 year: 60–450
4	70–110	13 year–adult: 8.8–10.2	13 year–adult: 2.7–4.6	13 year–adult: 40–180
5	200–300	8.8–9.7	1–12 year: 4–6 > 12 year: 3.5–5.5	

Abbreviation: PTH, parathormone.

PREVENTION

Early diagnosis of CKD and management of its complications are critical in delaying or preventing progression to ESRD. While some factors influencing the progression of CKD are not modifiable, those factors that are should be addressed early. Nonmodifiable risk factors for disease progression include the underlying cause of CKD, with acquired glomerular diseases leading to more rapid CKD progression compared to CAKUT. Other nonmodifiable risk factors include more advanced CKD stage, African-American ethnicity and puberty. Hypertension is an important modifiable risk factor. Control of hypertension is shown to reduce the rate of decline of GFR in adults and children. Proteinuria is another modifiable risk factor for progression. Antagonists of the renin angiotensin system are beneficial in patients with CKD, both for their antihypertensive and antiproteinuric effects, and are key agents in slowing disease progression. Other factors which may also affect disease progression and should be addressed include the aforementioned complications of CKD: metabolic acidosis, dyslipidemia, altered calcium phosphate metabolism and anemia.

OUTCOME

Data from a large cohort of children with CKD in Italy showed that nearly 70% of the cohort progressed to ESRD by the age of 20 years. The outcome for children who have progressed to ESRD depends largely on whether renal replacement therapy is readily available, with rates of renal replacement therapy and kidney transplantation being generally low in developing countries. Renal transplantation is the preferred treatment for ESRD when possible, as it offers advantages over dialysis both in regards to survival as well as quality of life. When renal transplantation is not possible or while patients are awaiting transplantation, either peritoneal dialysis or hemodialysis may be used as the form of renal replacement therapy.

IN A NUTSHELL

1. Children with CKD are asymptomatic until they progress to advanced CKD making early diagnosis and intervention challenging yet imperative.
2. There are several estimating equations for children with CKD which can help categorize stages of CKD in those above the age of 2 years.
3. Congenital structural anomalies of the kidney and urinary tract are the most common cause of CKD in children.
4. Careful monitoring is required to manage complications of CKD namely: anemia, growth impairment, mineral and bone disorders, hypertension and electrolyte abnormalities.
5. Treatment of hypertension and proteinuria can slow the decline of renal function.
6. Renal transplantation is the treatment of choice in children with ESRD.

Chapter 41.22
End-Stage Renal Disease
Kirtida Mistry, Asha Moudgil

CHRONIC DIALYSIS

End-stage renal disease (ESRD) is the most advanced stage of chronic kidney disease (CKD) when glomerular filtration rate (GFR) is less than 15 mL/min/1.73 m^2. Irrespective of etiology, all ESRD patients eventually develop symptoms and signs of uremia. Once ESRD develops, lifesaving renal replacement therapy (RRT) in the form of either dialysis or renal transplantation is required. The indications for initiating dialysis are listed in **Box 1**.

Dialysis refers to the movement of solutes across a semipermeable membrane, resulting in removal of waste products or uremic toxins and correction of electrolyte disturbances. Additionally, dialysis provides the capability for fluid removal or ultrafiltration. Two forms of chronic dialysis modalities are available for management of ESRD: hemodialysis (HD) and peritoneal dialysis (PD). In general, HD is performed by skilled staff in a dialysis unit, whereas PD is a form of home therapy. There is a growing pediatric population in more developed countries performing home HD. These tend to be patients without psychosocial contraindications to home dialysis, but in whom for various medical reasons PD is not an option. The factors determining the choice of dialysis modality are listed in **Table 1**. Worldwide, PD has been the predominant modality used in children, but the proportion of patients on maintenance HD is rising. All chronic dialysis patients, irrespective of modality, require meticulous medical management of the complications of ESRD (Chapter 41.21).

BOX 1 **Indications for initiation of chronic dialysis**

- Estimated GFR less than 15 mL/min/1.73 m^2
- Estimated GFR greater than 15 mL/min/1.73 m^2 with any of the following:
  - Fluid overload including: (i) worsening edema due to oliguric renal failure; (ii) pulmonary edema; (iii) congestive heart failure; (iv) hypertension due to fluid overload
  - Uncontrolled hyperkalemia, metabolic acidosis or hyperphosphatemia
  - Symptoms and signs of uremia
  - Inability to maintain adequate nutrition
  - Poor growth and development.

Table 1 Factors determining the choice of chronic dialysis modality

Medical
• Ability to obtain vascular access
• Integrity of the peritoneal membrane
• Presence of comorbidities
• Patient's age and size
• Expertise of staff and availability of equipment

Psychosocial
• Patient and family adherence
• Family and social support structure
• Psychiatric illness in patients and/or caregivers
• *Living circumstances:* Presence of hygienic space for home dialysis
• Parental or caregiver preference
• Economic factors

Chronic Peritoneal Dialysis

Peritoneal dialysis utilizes the patient's peritoneal surface as the semipermeable membrane for solute clearance and ultrafiltration. The process involves instillation of sterile biocompatible fluid (dialysate) into the abdominal cavity via a cuffed PD catheter **(Fig. 1)**. The fluid dwells in the peritoneal cavity for a period of time allowing for solute and water exchange to occur and is subsequently drained by gravity and discarded (PD effluent). Solute clearance occurs primarily by simple diffusion from high to low concentration, whereas ultrafiltration is achieved by establishing an osmotic gradient using dialysate with varying dextrose concentrations. The therapy is performed daily.

Contraindications to PD are listed in **Table 2**. There are essentially two forms of chronic PD: (1) continuous ambulatory PD (CAPD) and (2) automated PD (APD). The former does not require a cycler and requires fewer consumables and thus is more affordable and accessible for patients in less developed countries. Exchanges are performed manually during the day and the patient has a prolonged overnight dwell. APD involves an automated cycling device that performs the prescribed therapy, usually when the patient is asleep. **Table 3** lists the complications of PD.

Chronic Hemodialysis

Hemodialysis is a form of dialysis where access is required to the patient's bloodstream, either via a central venous HD catheter or
Figure 1 Peritoneal dialysis. A biocompatible and sterile fluid called dialysate is instilled into the peritoneal cavity via a dialysis catheter. It dwells there for a prescribed period of time allowing for solute and water exchange to occur, and subsequently drains out and is discarded (effluent). The arrows depict the direction of fluid flow

Table 2 Contraindications to chronic peritoneal dialysis

Absolute contraindications
• Omphalocele or gastroschisis
• Bladder exstrophy
• Irreparable abdominal hernias, diaphragmatic hernia or pleuroperitoneal fistula
• Peritoneal membrane failure, sclerosis or excessive adhesions limiting dialysate flow
• Lack of competent caregiver to perform dialysis in a child

Relative contraindications
• Nonadherence to medical therapy
• Lack of living conditions conducive for performing home dialysis
• Impending abdominal surgery
• Inflammatory or ischemic bowel disease
• Imminent kidney transplant
• Abdominal wall or skin infections
• Morbid obesity
• Severe malnutrition
• Peritoneal leaks

Table 3 Complications of dialysis

Peritoneal dialysis
• *Infection:* Peritonitis, exit site and tunnel infections • Abdominal wall hernias; peritoneal fluid leaks; hydrothorax • Pain • Hemoperitoneum • Malnutrition due to protein loss and emesis • Hyponatremia • Peritoneal dialysis catheter occlusion, migration or displacement
Hemodialysis
• Hypotension or hypertension • Muscle cramps, headache, nausea and emesis • Dialysis disequilibrium syndrome, most commonly during the first few treatments • Pruritus • Iron deficiency anemia, hemolysis • *Access related complications:* Infection, thrombosis and malfunction • Hypoxemia, cardiac arrhythmias and chest pain • Air embolus

a surgically created arteriovenous fistula or graft. The principle of solute clearance primarily by diffusion is identical to that in chronic PD, while ultrafiltration occurs by a hydrostatic pressure gradient created across the dialyzer membrane by the HD machine **(Fig. 2)**. HD treatments are usually performed at least three times per week, although evidence is mounting for improved outcomes and quality of life with more frequent dialysis. A water purification system is required for HD so as to minimize patient exposure to chemical and infectious contaminants. Chronic HD results in relatively more hemodynamic instability and risk of blood loss, and is hence more challenging to perform in infants and small children, than PD. Complications of chronic HD are listed in **Table 3**.

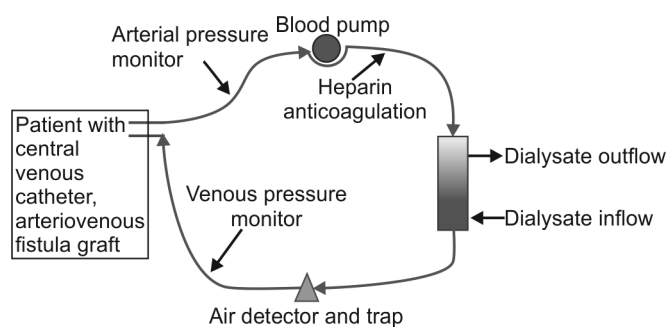
Outcomes of Pediatric Chronic Dialysis
When children develop ESRD, mortality is increased by 30-fold compared to their peers without ESRD. Prognosis of ESRD has improved significantly over the past decades due to ready access to chronic dialysis. Despite this, the overall mortality of children with ESRD is about 4% in the United States, being highest in the youngest children. Compared with patients on dialysis, renal transplant is associated with four-fold lower mortality.


Figure 2 Schematic of hemodialysis circuit. Hemodialysis requires access to the patient's blood stream, by either a central venous double lumen catheter or using a surgically created arteriovenous fistula or graft. The arrows depict the direction of blood and dialysate flow. Blood is pumped out of the patient via the access line and enters the dialyzer. The tubing through which the blood flows in the dialyzer is bathed in dialysate, and this is the site of solute exchange and water removal. Blood exiting the dialyzer is free of uremic toxins and is returned to the patient via the return line. Monitoring systems are built into the circuit for monitoring and patient's safety

RENAL TRANSPLANTATION
Compared to dialysis, transplantation is associated with lower morbidity and improved growth and nutrition, school performance and quality of life. Preemptive transplant from a living donor can help bypass dialysis and is cost-saving. Children are ideal candidates for transplantation due to lack of co-morbidities. Contraindications to transplant are listed in **Table 4**.

Recipient Evaluation
Extensive work-up and health optimization is needed for a child prior to transplantation. Determining the cause for ESRD helps plan management for diseases with potential for recurrence [focal segmental glomerulosclerosis, atypical hemolytic uremic syndrome, membranoproliferative glomerulonephritis (GN)]. The urinary bladder is evaluated by postvoid ultrasonography, voiding cystourethrogram and, if required, by urodynamic studies. Appropriate reconstruction surgeries such as bladder augmentation may be required prior to transplantation. Bilateral nephrectomy is indicated in children with chronically infected or large polycystic kidneys, severe nephrotic syndrome, intractable hypertension, nephrolithiasis or polyuria. Children should be screened for infections including tuberculosis, human immunodeficiency virus (HIV), hepatitis B and C, cytomegalovirus, Epstein-Barr virus and varicella, and receive age appropriate immunizations.

The donor and the recipients should be blood group compatible as incompatibility results in hyperacute rejection. Genetic differences between individuals are recognized by dissimilarities in the major histocompatibility complex human leukocyte antigens (HLA) antigens of class I and class II. HLA mismatches between the donor and the recipient determine the strength of immunologic response and potential for development of detrimental de novo donor specific anti-HLA antibodies after transplant. Recipients are tested for anti-HLA antibodies to determine their sensitization to HLA antigens, which can occur in response to blood transfusions or previous transplant. These antibodies preclude transplant from donors carrying these specific HLA molecules. Additionally, each recipient is cross-matched with the prospective donor to ensure absence of anti-HLA antibodies to their specific donor.

The family's inability to comply with medical therapy should be addressed prior to transplant as nonadherence is the most important cause of graft failure, particularly in adolescents. Some children need cardiac, pulmonary and other evaluations. Growth and nutrition should be optimized as malnutrition and obesity pose risks following transplantation.

Donor Source and Evaluation
Donors can be living-related, unrelated or altruistic. Their work-up includes a thorough medical history, physical examination,

Table 4 Contraindications to transplantation

Absolute
• Acute infection • Recent untreated malignancy (need to wait 2–5 years) • Progressive neurologic disease; persistent vegetative state • Multiorgan failure
Relative*
• HIV infection (can be controlled with medications) • Hepatitis B and C infection (can be controlled with antiviral medications) • Nonadherence with medical therapy (counseling)

*Transplantation can be undertaken after addressing these issues.
Abbreviation: HIV, human immunodeficiency virus

blood group and HLA typing, liver and kidney function tests including urinalysis and 24 hours urine protein analysis, screening for infections (HIV, hepatitis B and C, syphilis and tuberculosis) and age appropriate malignancies and cardiac evaluation. Renal anatomy is defined by ultrasonography and renal vascular anatomy by contrast angiography by spiral CT or MRI.

Allografts from living (related/unrelated) donors have a longer half-life compared to those from deceased donors. This is attributed to healthier organs, avoidance of graft injury during dying process and minimization of cold ischemia time. Injury due to death, ischemia and reperfusion increase the risk of acute rejection. Compatible blood group and a negative cross-match are desired for a successful transplant. While HLA matching is not required, HLA identical grafts have a longer half-life compared to less well-matched grafts. The practice of *transplant tourism* involving purchase of organs from unknown living donors is condemned by the *Transplant Societies in the Declaration of Istanbul.*

Procedure

Donor nephrectomy is done by open or by laparoscopic procedure. Depending upon recipient size, the allograft is placed either in the iliac fossa or higher up in the retroperitoneum and the donor artery and vein are connected to the recipient's iliac vessels or aorta and inferior vena cava. The ureter is anastomosed to the bladder, or rarely to the native ureter or urinary conduit. Intraoperatively, liberal amount of intravenous (IV) fluids are given and central venous pressure maintained between 10 cm and 15 cm H_2O to maintain perfusion to the transplanted organ. Postoperatively, adequate fluid and electrolyte management and proper blood pressure support is important to ensure adequate allograft perfusion to optimize graft function. Immunosuppression is most potent at the onset and becomes less intense afterwards. Induction therapies used at transplant include either polyclonal (thymoglobulin) or monoclonal (anti-IL2 receptor) antibodies with high dose methylprednisolone; the choice of induction depends upon the immunologic risk of the recipient. Maintenance immunosuppression uses a combination of a calcineurin inhibitor (tacrolimus or cyclosporine), an antiproliferative drug (mycophenolate mofetil or azathioprine) and tapering doses of prednisolone. Children should be monitored for postoperative complications, graft function, side-effects of immunosuppressive and other medications and need ongoing management of CKD to ensure long-term success of transplant.

Complications and Outcome

Delayed graft function due to acute tubular necrosis may occur due to hypotension in the donor or recipient and is common in organs from deceased donors, particularly those with prolonged cold and warm ischemia time. Acute rejection in the first few months has become uncommon due to use of potent immunosuppression. Its occurrence after many months is usually related to nonadherence with medications. Acute rejection is suspected when there is sudden increase in serum creatinine, decrease in urine output, fever, graft tenderness, increase in blood pressure and proteinuria; the diagnosis is confirmed on renal biopsy. Patients on potent immunosuppression are also at risk of opportunistic or community acquired viral and bacterial infections. They need to be screened for side effects of medications, and steps taken to ensure growth and nutrition, and bone and cardiovascular health.

IN A NUTSHELL

1. End-stage renal disease refers to the most advanced form of CKD when GFR is less than 15 mL/min/1.73 m^2. ESRD presents with uremic complications involving multiple organ systems, and requires institution of RRT in the form of HD, PD or renal transplantation.
2. Renal transplantation is associated with reduced risk of mortality and morbidity and improved quality of life compared to chronic dialysis.
3. Acute rejection is the most common complication following transplantation, noted usually in the first 3 months, but may occur later with nonadherence to immunosuppression.
4. Optimal long-term management of transplant recipients involves minimizing immunosuppression without risking rejection, blood pressure control, maintain nutrition, growth and optimize quality of life, and screen for infections, dyslipidemia, hyperglycemia, proteinuria and malignancies.

Section 42 NEUROLOGICAL DISORDERS

Section Editors Satinder Aneja, Suvasini Sharma

Chapter 42.1
Approach to Neurological Disorders
Suvasini Sharma, Satinder Aneja

A comprehensive neurological evaluation which includes a detailed history, physical examination and the judicious use of investigations is the key to reach the diagnosis in children with neurological problems. A plethora of investigations such as MRI, CT, EEG, electrophysiological studies, metabolic testing, etc. are available; however, the use of these should be guided by clinical judgment and the likely etiological possibilities. In this chapter, the general clinical approach to a child with neurological problems is discussed. In the following chapters, the use of various investigations which are useful in pediatric neurology will be covered. The subsequent chapters will cover the various diseases of the central nervous system.

NEUROLOGICAL HISTORY

For reaching a neurological diagnosis, the one most important prerequisite is a thorough history. History should be obtained from the parents (especially the mother), the child (if older than 3 years of age), and other caregivers (e.g., grandparents). The affected child must always be given the opportunity to describe his symptoms. If the child participates actively, the child's level of understanding and description of his symptoms help the physician to make a judgment of the child's intellectual level and language skills.

The history should begin with the details of how information was obtained, demographic details and handedness for children older than 3 years of age. History should detail all presenting complaints in sufficient detail. Every symptom should be carefully analyzed by asking the patient/parents relevant questions. The common symptoms in neurological diseases include headache, seizures, weakness, pain, vision and hearing problems, squint, stiffness or limpness or limbs, sensory abnormalities, bladder and bowel problems. Relevant non-neurological symptoms must also be enquired about. For example, in a child with dystonia and rigidity, the presence of jaundice indicates Wilson's disease as a likely possibility. In a patient with chorea, the presence of arthritis and photosensitive rash points to systemic lupus erythematosus as a likely possibility.

A large subset of children present with developmental delay, deviant development, or regression. Diseases affecting the child's brain must be understood in the developmental context. The antenatal and perinatal history must include the details of the pregnancy, labor, status at birth, need for resuscitation, lethargy, seizures, neonatal intensive care unit (NICU) stay, jaundice, etc. In case of home delivery the details are ascertained from mother and other family members as records are often not available. A

sole history of delayed cry is not enough to attribute the etiology to perinatal asphyxia. The physician must enquire whether the child had any features of neonatal encephalopathy, i.e., lethargy, feeding difficulties, seizures, etc. along with the history of delayed cry.

The developmental history is a very important part of the neurological evaluation. The achieved milestones in various domains—gross motor/fine motor/language/social must be elicited. It is helpful to start with the most recent milestones as the recall is better. The physician should determine whether the delay is global (all domains) or pure motor (e.g., neuromuscular)/language (e.g., deafness)/social (e.g., autism). Any dissociation in the various spheres of development must be looked for. The parents should also be asked about the vision and hearing function. Behavior problems such as hyperactivity, aggressive behavior and communication difficulties must also be asked about. In the school going child, the child's academic performance and any recent worsening also needs to be asked about. The latter could be an early sign of a neurodegenerative disorder.

The past history is important because neurologic symptoms may be related to systemic diseases. A three-generation family history and pedigree charting helps to understand and know about possible hereditary disorders. In the Indian context history of contact with tuberculosis would be relevant in practically all children. Depending on the presentation relevant family history could include history of epilepsy, sibling deaths, muscular dystrophy, degenerative disorders, migraine, early cardiac deaths or cerebrovascular disease, etc. The questions that need to be answered by history are discussed here:

Q1. At What Age did the Problem Start?
Early onset problems are likely to be due to perinatal insult, intrauterine problems and brain malformations. Infective, metabolic/degenerative and vascular processes can occur in any age group, but the manifestations will vary according to the age at presentation. Establish that the child was normal prior to the disease onset by means of the developmental history, school performance and past history.

Q2. How did the Symptoms Start; i.e., How was the Onset—Acute, Subacute or Insidious?
Acute onset implies an onset within a few hours or days. Acute onset disorders are likely to be of infective, parainfectious, vascular, or traumatic etiology. Insidious and chronic onset means the problem has been there for months to years. Often the parent cannot exactly remember when the problem started exactly. Chronic onset problems are more likely to be degenerative.

Q3. What Parts of the Neuroaxis are Involved?
Establish what parts of the neuroaxis are involved. Decide whether the process is diffuse, focal or multifocal. The presence of seizures, aphasia, cognitive decline and behavioral problems indicate involvement of the cerebral cortex. Altered sensorium or impaired consciousness indicates involvement of the reticular

activating system. The presence of cranial nerve deficits indicates involvement of the brainstem or the supranuclear pathways. Focal neurological deficits are likely due to vascular pathology such as stroke or space occupying lesions such as tumors. In patients with neurodegenerative disorders, white matter disorders (e.g., leukodystrophies) are characterized by early onset of spasticity, and motor regression while cognitive decline and seizures occur late in the course of illness. In gray matter neurodegenerative disorders (e.g., neuronal ceroid lipofuscinosis), cognitive decline and seizures occur early, and motor function is affected late in the course of illness. Basal ganglia disorders (e.g., Wilson's disease) are characterized by rigidity, dystonia, and involuntary movements such as tremors and choreoathetosis. Cerebellar disorders are characterized by the presence of ataxia, hypotonia and intention tremors.

Q4. Is the Disease Process Static, Progressive or Intermittent?

Static processes imply a onetime insult, e.g., perinatal asphyxia, traumatic brain injury, or meningoencephalitis. After the insult, the patient may improve, or remain at the same level, but there is no worsening. In progressive disorders, the symptoms continue to worsen with time. The likely etiology is degenerative and metabolic disorders; rarely this may be the presentation with slowly growing neoplastic lesions and toxin exposure. In intermittent disease presentations, the child is well in-between the episodes. Examples include paroxysmal disorders such as epilepsy and migraine.

EXAMINATION

The neurological examination has to be tailored to patient's condition, age, setting (OPD/ward/Casualty/ICU). It is neither *necessary* nor *possible* to do all aspects of neurological examination in all children. For example, in a child who has presented with a history of seizures, a detailed sensory testing will only tire the patient, and not add to any useful information.

The traditional neurological examination can be done in older children and adolescents, however, the scheme and detail of examination needs to be modified for infants and young children. The sequence of examination should be flexible and should be determined by the child's mood and comfort level. It is beyond the scope of this chapter to cover all aspects of the traditional neurological examination (The reader is referred to the appropriate sources at the end of this chapter). The schema for neurological examination of the older child is given in **Box 1**. Basic aspects of the neurological examination of the older child and some techniques of neurological examination of children less than 2 years of age will be discussed. The results of the neurological examination need to be interpreted in the developmental context of the child's maturing nervous system.

General Physical Examination

Features of facial dysmorphism and neurocutaneous stigmata must be looked for. Neurocutaneous markers include café au lait spots, ash leaf macules, neurofibromas, Lisch nodules in the iris, patterned skin nevi (e.g., whorled lesions in hypo-melanosis of Ito), and hemangiomas. Coarse facies are seen in mucopolysaccharidosis, GM1 gangliosidosis and mucolipidosis. Hair abnormalities must also be looked for—in Menkes disease, the hair is sparse, hypopigmented and kinky. Eye examination must be done to look for cataracts (galactosemia), Kayser-Fleischer rings (Wilson disease) and telangiectasia (ataxia telangiectasia).

BOX 1 Schema of neurological examination in older children/adolescents

- *Higher mental functions*
  - Level of consciousness
  - General behavior and appearance
  - Orientation
  - Attention span
  - Speech and language
  - Memory
  - Higher cognitive functions
  - Release reflexes
- *Cranial nerve examination (I to XII)*
- *Motor examination*
  - Bulk
  - Tone
  - Power
  - Deep tendon reflexes
  - Superficial reflexes
  - Abnormal movements
  - Gait
- *Sensory testing*
  - Touch
  - Pain
  - Temperature
  - Joint position sense
  - Vibration
  - Romberg's sign
  - Cortical sensation tests
- *Cerebellar signs*
- *Meningeal signs*
- *Examination of the autonomic nervous system*

Examination of the Head and Spine

Any skull defects must be looked for. The sutures must be palpated for any ridging or sutural diastasis. The head circumference should be measured and interpreted as normal, *microcephaly* (< –3SD below the median), or *macrocephaly* (> 2SD above). Careful examination of the head may help to differentiate primary from secondary (acquired) microcephaly. Macrocephaly may occur due to hydrocephalus, rickets, megalencephaly, subdural effusions and intracranial tumors. Children with hydrocephalus often have sun-setting sign in their eyes and distended scalp veins.

The shape and symmetry of the head must be observed for any abnormalities. Many young infants may have *plagiocephaly* because of positional asymmetry. *Craniosynostosis* occurs because of premature closure of the sutures and results in abnormally shaped head. Premature closure of the coronal suture prevents growth of the skull in the anteroposterior direction, and leads to a flattened appearing head called brachycephaly. Closure of the sagittal suture prevents growth in the lateral direction, resulting in a long narrow skull, called dolichocephaly.

The spine must be examined in all children with neurological illness, but this is especially important in children with paraplegia. A tuft of hair or dimple may indicate an underlying neural tune defect. Any localized vertebral tenderness must be looked for. The spinous processes must be felt, any kyphosis, lordosis, or scoliosis looked for. Lumbar lordosis is common in neuromuscular disorders such as Duchenne muscular dystrophy. Scoliosis may be seen in children with Duchenne muscular dystrophy, Friedrichs ataxia and cerebral palsy.

Systemic Examination

Systemic examination may provide important clues to the etiology. In a patient with chorea, the presence of a heart murmur may point to rheumatic heart disease. A child with stroke may

have an underlying congenital heart disease. A child with neurodegenerative disorder may have hepatosplenomegaly which points towards the possibility of lysosomal storage disease.

Neurological Examination: Observation

Much can be learned by simply observing the child unobtrusively during the history-taking procedure. The co-ordination of the child can be assessed. Movement disorders such as tics, tremor, choreoathetosis may also be noted. The gait should be noted as the child enters the room or walks about the room. This part of the examination also provides an opportunity to assess the child's behavior. Hyperactivity, impulsivity and easy distractibility may be noted. The mother-child interaction may also be observed at this time.

Higher mental functions Disorders of consciousness and examination of the unconscious child are detailed in a subsequent chapter. In the conscious child, testing for orientation, attention span, language, memory and higher cognitive abilities are performed depending on the age and presenting complaints of the child.

Cranial Nerve Examination

The olfactory nerve rarely requires testing in routine clinical practice. Testing of optic nerve involves the following components: visual acuity, color vision, field of vision, fundus and pupillary reactions. The visual acuity in various age groups is: at birth—20/2,000, 2 months of age—20/200, 1 year—20/60, 4 years—20/40; It reaches adult range by 5 years. Test charts include Snellen chart for distant vision and near card (Rosenbaum pocket vision screener held at 14 inches) for near vision. Visual fields are clinically tested by the confrontation test. Field defects are said to be homonymous if the same part of the field is affected in eyes, e.g., a right homonymous hemianopia means there is a field defect in the temporal field of the right eye and nasal field of the left eye. Whereas a bitemporal hemianopia would be a heteronymous field defect. Homonymous field defects are called congruous, if the field defects in both eyes match exactly or incongruous if the field defects do not match exactly.

Evaluation of the pupillary light reflex is critical in patients with coma, head injuries, stroke and brain tumors.

The third, fourth and sixth cranial nerves control the movements of upper eyelid, eyeball and pupils. They help in finding, fixating, focusing and following a visual target. These three nerves are tested together. The movements of both eyes, when they move together are known as *conjugate* movements. The conjugate movements are controlled by centers in the frontal lobe and brainstem (pons and midbrain). Any lesions in these regions lead to supranuclear gaze palsies. The medial and lateral recti have only the primary actions of adduction and abduction respectively. However, the other muscles (superior and inferior recti, and superior and inferior obliques) have multiple actions, because of their oblique attachments on the eyeball and consequent direction of pull. The superior rectus elevates (primary action) and adducts (secondary action). Hence, to test the pure elevation action of the superior rectus, the patient is first asked to abduct his eye (so that the secondary adduction action is counteracted) and then elevate. In the abducted position, superior and inferior recti act as pure elevators and depressors respectively. Similarly, in the adducted eye, the superior and inferior obliques act as pure depressors and elevators respectively.

The trigeminal nerve has a motor and a sensory component. The three divisions of V nerve (ophthalmic, maxillary and mandibular) innervate face, teeth, oral and nasal cavities, scalp up to vertex, intracranial dura, cerebral vasculature and proprioceptive inputs from masticatory muscles. The motor component innervates the four masticatory muscles: temporalis, masseter, medial pterygoid and lateral pterygoid. Chewing movements include: jaw protrusion and retraction, opening and closure and side-to-side movement. In addition, testing for the jaw jerk and corneal reflex are part of the trigeminal nerve examination.

The seventh nerve is mainly a motor nerve, supplying all the muscles concerned with facial expression on one side. The sensory component is small (the nervus intermedius of Wrisberg); it conveys taste sensation from the anterior two-thirds of the tongue and, variably, cutaneous sensation from the anterior wall of the external auditory canal. In upper motor neuron lesions, the upper part of the face is spared because of bilateral innervations. In lower motor neuron lesions, there is complete lack of ipsilateral facial movements. Eye closure is impaired, ipsilateral palpebral fissure is widened, ipsilateral nasolabial folds get obliterated and the angle of the mouth deviates towards the opposite unaffected side as patient tries to smile.

The vestibulocochlear nerve has two components, the vestibular and cochlear, blended into a single trunk. The cochlear portion subserves hearing; the vestibular nerve subserves equilibrium, coordination and orientation in space. Examination of the eighth nerve consists of hearing evaluation, tuning fork tests, and caloric testing for the vestibular system.

The glossopharyngeal and the vagus nerves are usually tested together. The pitch and quality of the voice, any nasal twang or pooling of secretions must be looked for. The palatal movements and position of the uvula need to be seen. The gag reflex is uncomfortable and should be done at the end of examination. In infants and young children, a feed can be observed. If the child appears to be swallowing well without any choking or drooling, testing for the gag reflex can be omitted. The afferent limb of the reflex is mediated by CN IX and the efferent limb through cranial nerves IX and X. The reflex center is in the medulla.

The spinal accessory nerve innervates the sternocleidomastoid and trapezius muscles. In unilateral sternocleidomastoid weakness, the child will fail to turn the head against resistance to the opposite side. Unilateral paresis causes little change in the resting position of the head. In bilateral weakness, child may not be able to lift his head off the couch. With trapezius weakness, there is drooping of shoulders with flattening of trapezius ridge.

The hypoglossal nerve supplies the musculature of the tongue. The patient should be asked to open his mouth and the surface, size, shape and position of the tongue should be observed. Look for any fasciculations. Fasciculations are common in anterior horn cell disease such as spinal muscular atrophy. The patient should be asked to protrude the tongue, move it in and out, from side-to-side and upward and downward. In case of unilateral weakness, tongue deviates towards the weak side on protrusion (because of the unopposed action of the normal genioglossus).

Motor Examination

Motor system examination begins with the observation of the muscle bulk. Any atrophy or hypertrophy should be looked for, and any asymmetries. In Duchenne muscular dystrophy, there is prominent hypertrophy of the calf muscles. In neuropathies, there is early atrophy of the extensor digitorum brevis muscle. There is long appearance of the face in some congenital myopathies and myotonic dystrophy.

Tone is defined as resistance to passive stretching. It excludes resistance as a result of joint, ligament, or bone problems. Methods to assess tone are described in **Box 2**. Hypertonia is defined as abnormally increased resistance to externally imposed movement about a joint. It may be caused by spasticity, dystonia, rigidity, or a

BOX 2 Assessment of tone

Assessment of tone

- *Posture:* Posture observe the spontaneous posture of the child when he is lying down in bed. A floppy hypotonic child will lie in a frog-like position. A hypertonic child will have extended lower limbs and may have scissoring.
- *Feel the muscles:* Normal muscles feel firm. Hypotonic muscles feel flabby and soft. Hypertonic muscles feel stiff.
- *Resistance to passive stretching:* Examine this in all four limbs. Especially look for asymmetries. If the tone appears increased, see if this increase is there throughout the range of motion, or there is an initial catch, and later give-way. If the tone is increased throughout the range, it is rigidity. If there is an initial catch, and then the tone reduces, it is spasticity. In spasticity, you will also find that the tone varies with the speed of stretching (velocity dependent). In infants also look for the truncal tone. Young infants with evolving cerebral palsy may have axial hypertonia with limb hypotonia and vice versa.
- *Flappability:* Shake the limb to and fro and observe the movement at the distal joint, e.g., shake the forearm, and observe the movement at the wrist. If there is hypotonia, the movement at the wrist (i.e., flappability) will be increased. If there is hypertonia, the movement at the wrist will be decreased.

Apart from the methods mentioned above, in infants, the range of motion can be quantified using angles as described by the Amiel-Tison method. Also, some maneuvers are useful in demonstrating the hypotonia in floppy infants, e.g., pull to sit, vertical suspension and ventral suspension.

Table 1 Muscle power grading by Medical Research Council (MRC)

Grade	Definition
5	Normal strength
4	Muscle holds the joint against a combination of gravity and resistance
3	Muscle cannot sustain the joint against resistance, but moves the joint fully against gravity
2	Muscle moves the joint when gravity is eliminated
1	A flicker of movement is seen or felt in the muscle
0	No movement

Presence of anti-gravity movements and level of power help in this assessment. Peripheral hypotonia is associated with paralysis (manifest in infants as reduced spontaneous and antigravity movements) and central hypotonia is nonparalytic.

For testing *muscle power*, the patient should be seated comfortably on firm surface and appropriately undressed to allow visualization of the muscle. In bed-bound patients, power grades can be approximated. To test distal muscle, the proximal limb should be stabilized. For grading the muscle power, the most frequently used scale is Medical Research Council scale **(Table 1)**. This is based on gravity resistance techniques.

The *deep tendon reflexes*, also known as muscle stretch reflexes, are tested next. When a normal muscle is passively stretched, its fibers resist the stretch by contracting. In the monosynaptic stretch reflex, sudden lengthening stretches the muscle spindles, which send impulses via the primary spindle afferents into the spinal cord. The spindle afferents synapse directly on the alpha motor neurons, innervating the muscle, causing a reflex contraction of the muscle. The patient should be comfortable, relaxed and properly positioned. The muscle should be exposed. The hammer strike should be quick, crisp and forceful (as necessary). It is important to look for the muscle contraction, not just the movement at the joint. The optimal position is usually midway between ranges of motion. The adequate stimulus must be delivered at the proper spot. Reinforcement techniques, such as the Jendrassik maneuver can be used if the reflexes are not elicitable. The commonly tested deep tendon reflexes in clinical practice include the knee jerk, the ankle jerk, the biceps, the triceps and the supinator reflexes. Excessively brisk reflexes occur with upper motor neuron lesions. Remember however that such reflexes may also occur with fright, agitation and anxiety. Hence, brisk reflexes are of pathological significance only if taken in conjunction with features of upper motor neuron disease such as spasticity and extensor plantar responses. Reflexes may be absent or reduced in lower motor neuron lesions, peripheral neuropathy. Reflexes may also be absent in the *spinal shock* phase after spinal injury or acute transverse myelitis. An extensor plantar response often appears long before the reflexes return.

In young infants, the predominant flexor tone of early infancy almost invariably suppresses the triceps jerk entirely, and the ankle jerk may be difficult to elicit. Young children are often relatively hypotonic and their reflexes may be depressed by adult standards.

The superficial reflexes which are tested include the corneal reflex, the abdominal reflexes, the plantar responses, the cremasteric reflex and the anal reflex. An extensor plantar response indicates disturbance in the upper motor neuron system. However, the plantar response is normally extensor in infants under 1 year of age.

Finally, the gait of the patient should be observed. The patient should be observed walking, back and forth normally in a corridor and turning right and left. The patient should also be asked to walk

combination of these. *Spasticity* is a velocity-dependent resistance of a muscle to stretch. In spasticity, if the passive movement is made slowly, there may be little resistance. If however, the movement is made quickly, there may be an initial increased resistance followed by a *catch*. Spasticity can vary depending on a child's state of alertness, activity, or posture. Spasticity can be increased by anxiety, emotional state, pain, surface contact, or other nonnoxious sensory input. Spasticity is caused by lesions in the corticospinal pathways (the pyramidal system). *Rigidity* is a diffuse increase in resistance to passive stretching that occurs primarily with lesions that involve the basal ganglia (the extrapyramidal system). The increased tone affects both agonist and antagonist muscles and is equally present throughout the range of motion at a given joint. The increased tone is constant from beginning to the end of the movement and does not vary with the speed of the movement. *Dystonia* is used to describe spontaneous, involuntary, sustained muscle contractions that force the affected part of the body into abnormal twisted movements or postures, sometimes with co-contraction of agonists and antagonists. Dystonia occurs because of disturbance in the extrapyramidal system.

Tone can be markedly influenced by sleep, drugs, stress, excitement or systemic illness. The resting tone changes during early infancy. The flexed tone and posture of the newborn gradually decreases until normal mature tone is seen by about the age of 6 months.

In addition to appendicular tone, the axial tone in the infant is tested by supporting the trunk in supine, prone, vertical suspension and ventral suspension and observing the position of the infant. The examiner also observes the head and trunk posture and movement when the infant is held in an upright sitting position. These maneuvers and the traction response assess active tone (power) as well as tone. Hypotonia can be associated with dysfunction of both central and peripheral nervous system or musculoskeletal system. An attempt should be made to determine however whether the hypotonia is central (related to central nervous system pathology) or peripheral (related to peripheral nervous system) or both.

on his toes and heels, hop and tandem walk. The child is observed for type of gait (e.g., wide based or narrow) and also for associated movements of arms and any asymmetry.

Sensory Examination

Sensory system examination requires a lot of cooperation from the patient. There is a lot of subjectivity in this testing. Detailed sensory testing is not needed in each and every patient. It is needed in searching for a level of lesion in a child with suspected spinal cord disease, patient with suspected syringomyelia, or in delineating a peripheral nerve or plexus lesion. One should explain to the patient about the procedure and should take the patient into confidence. The test should be demonstrated to him/her with eyes open. Then patient should be requested to close his/her eyes during the actual testing.

Two ascending tracts are important components of sensory system. These are the spinothalamic tract (pain, light touch and temperature) and the dorsal columns (vibratory sensation, position sense and discriminative sensation). Sensory deficit from a spinal nerve lesion is distributed in a dermatome pattern. Sensory deficit from a peripheral nerve lesion is in the distribution of that peripheral nerve. Sensory deficit from a polyneuropathy will have a stocking and glove distribution because the longest axons are the most affected.

Cerebellar Signs

Dysarthria in cerebellar disease consists of slowness, slurring of words and scanning speech. In scanning speech, the patient's voice varies from a low volume to a high volume as if scanning from peak-to-peak. Cerebellar disease produces a spluttering *staccato speech*. For example the word *artillery* will be spoken as *ar-til-lery*. Cerebellar lesions result in nystagmus, dysmetria of saccades, jerky pursuit eye movements. Cerebellar nystagmus occurs predominantly during volitional use of the eyes and thus is gaze evoked.

Cerebellar lesions impair the gait and stance (the standing posture). To compensate for unsteadiness of stance and gait, the patient assumes a broad-based stance and a broad-based gait. Subtle abnormalities may be better picked by asking patient to do tandem walking.

Dysmetria (past pointing) should be looked for. The patient, in seeking a specific end point, such as the nose on the finger-to-nose test, frequently *undershoots* or *overshoots* the target because of failure to control the muscular contractions that set the distance. *Intention tremor* is a type of tremor that occurs predominantly on voluntary activity and the tremor reaches its peak of oscillation toward the end of the movement. It disappears at rest. It is noticed dramatically when reaching for objects (such as when performing finger-to-nose testing).

Dysdiadokokinesia means difficulty in performing rapid alternating movements. It means only incoordination of muscular contractions during rapid alternating movements. Cerebellar lesions produce inaccuracies in rapidly repeated movements.

Incoordination of limbs is tested by the finger nose test for the upper limb and heel-shin test for the lower limbs. The heel-to-shin test for in coordination supplements gait testing in bedridden patients. Patients with cerebellar disease are often hypotonic. Hypotonia is much more apparent with acute than with chronic lesions. Pendular reflexes result because of the presence of cerebellar hypotonia. In a normal patient, the leg normally stops swinging after one or two excursions during the knee jerk. In a patient with cerebellar disease, the leg swings to and fro several times, like a pendulum, without the normal checking of the excursions by muscle tone.

Table 2 Primitive reflexes with age of appearance and disappearance

Reflex	Appears	Disappears
Grasp	Birth	3–4 months
Moro	Birth	3–4 months
Rooting	Birth	3–4 months
Stepping	Birth	3–4 months
Placing	Birth	3–4 months
Sucking	Birth	3–4 months
Asymmetric tonic neck reflex	Birth	3–6 months
Landau reflex	3 months	1–2 years

Meningeal Signs

Meningeal signs are present when the meninges are inflamed from infection or the presence of blood. *Meningismus* is the presence of meningeal signs. *Meningism* is the presence of neck stiffness in the absence of meningeal inflammation. The various maneuvers used to elicit meningeal signs produce tension on inflamed and hypersensitive spinal nerve roots and the resulting signs are postures, protective muscle contractions or other movements that minimize the stretch and distortion of the meninges and roots. These include neck rigidity, Kernig's sign and Brudzinski's sign.

Assessment of Primitive Reflexes and Postural Responses

These need to be performed in young children, and children with developmental delay and suspected cerebral palsy. Primitive reflexes are normally present in the newborn but these normally disappear by 3 months to 1 year of life. These primitive reflexes have to be lost so that voluntary functions can be acquired. Abnormal persistence is a clue to a likelihood of developing cerebral palsy. The primitive reflexes, with the age of appearance and disappearance are summarized in **Table 2**. The abnormalities to be noted are (i) continued presence of a reflex that should have disappeared, (ii) asymmetric response or (iii) absence of an expected reflex.

Postural responses are mechanisms which children develop to support themselves against gravity and to develop equilibrium and balance. The appearance of these at the appropriate times is essential for normal development. Some of the important postural mechanisms include the tilt reactions. Tilt reactions develop when the child is 9–12 months of age. With the patient in sitting position, the patient is tilted to one side, then forward and back. During the sideways tilt, the child's arm abducts and extends to the side as a protective mechanism. This test also helps in early detection of subtle hemiplegia as the reaction will be absent on the affected side. During the forward tilt, the child extends the head and back. During the backward tilt, the child flexes the head and back.

Motor Screening Examination

This can be performed in children older than 4 years of age. If any abnormalities are found, then detailed testing needs to be performed. Whenever possible, the examiner should try and demonstrate what needs to be performed. The child needs to be encouraged and praised to improve cooperation.

- The child should be asked to hop, first on one foot, and then the other.
- He should be asked to tandem-walk, toe-walk and heel walk.
- The child should be asked to rise from the squatting position. A Gower's sign suggestive of proximal muscle weakness may be seen.

- The child should be asked to stand with the feet close together, eyes closed and arms stretched out. The Romberg's sign and any abnormal movements may be looked for.
- The child should be asked to perform the finger-nose-finger test.

Schema of Neurological Examination of Child Younger than 2 Years of Age

In a young child, the child should be observed carefully while on the mother's lap during the history taking process. Some assessment of cranial nerve abnormalities, squint, facial dysmorphism, quality and symmetry of limb movements and any abnormal movements and postures may be observed. The examination must initially be continued while the child is still in the mother's lap. The head, muscle tone, deep tendon reflexes, plantar responses, sensation, response to sound and visual tracking can be tested. Methods of tone assessment have been described in **Box 2**. The pupillary responses should be noted. Hand the child a toy. Early handedness (before the age of 2 years) is a sign of congenital hemiplegia. Look for the maturity of the grasp and see if it is age-appropriate.

After this, the mother is asked to place the child on the examination table. Here the spontaneity of limb movements, the quality of movements, the presence of antigravity movements, the presence of any asymmetry, the developmental reflexes, response to pull to sit, traction response are assessed. Systemic examination should also be completed at this stage. Head circumference should be measured. Sensory examination in infants is difficult and usually limited to gross touch and pain.

In the end, the child is placed on the floor and assessment of crawling, walking and running is done. The child may be encouraged to do this by rolling a ball or a toy across the floor so that he tries to retrieve it. Asymmetries, waddling, foot drop, or scissoring may be noted.

IN A NUTSHELL

1. A comprehensive neurological evaluation which includes a detailed history, physical examination, and the judicious use of investigations is the key to reach the diagnosis in children with neurological problems.
2. A thorough history is the best pointer towards the diagnosis, and guides the examination and investigation techniques to be used.
3. The developmental history of the child (premorbid) and current status (normal or regression) is an essential component of evaluating a child with neurological problems.
4. The chief aspects of the child's disease that need to be obtained by history include the age at onset, the type of onset, the parts of the neuroaxis involved and the type of progression.
5. Neurological examination needs to be tailored to the child's age, general condition and likely etiological possibilities.
6. The traditional neurological examination can be done in older children and adolescents, however, the scheme and detail of examination needs to be modified for infants and young children.

Chapter 42.2
Cerebrospinal Fluid and Neurophysiology
Anita Choudhary

CEREBROSPINAL FLUID

Cerebrospinal fluid (CSF) is principally formed by secretion from ependymal cells of choroid plexus of the lateral, third and fourth ventricles. The rate of CSF formation in healthy adult is approximately 20 mL/hour. Total CSF volume in full term neonate is approximately 50 mL, whereas in adult it is approximately 150 mL.

Cerebrospinal fluid provides buoyancy and protects brain tissue from injury (from head movement and trauma), it redistributes in response to acute change in any intracranial content (helps to maintain normal intracranial pressure), serves as a route for the transport of centrally produced hormones, supplies nutrients to nervous system tissues and removes waste metabolites.

Flow of Cerebrospinal Fluid

Cerebrospinal fluid flows from the lateral ventricles into the third ventricle through the interventricular foramina (foramina of Monro) and then into the fourth ventricle through the cerebral aqueduct. From fourth ventricle CSF enters central canal of spinal cord or exits the ventricular system through the lateral foramina of Luschka and the midline foramen of Magendie to enter subarachnoid space via cisterns. Flow of CSF is mainly downward posterior to the spinal cord and upward anterior to the cord, finally reaching the basal cisterns, from where it flows mainly over the brain convexity.

Cerebrospinal Fluid Examination

Cerebrospinal fluid examination is the most important investigation for diagnosis of meningitis and encephalitis. It is often helpful in evaluating CNS demyelinating disorders, Guillain-Barré syndrome, intracranial hypertension (as in idiopathic intracranial hypertension), neurodegenerative disorders, collagen vascular diseases, leptomeningeal carcinomatosis, subarachnoid hemorrhage (in patients with negative CT scan) and neurotransmitter diseases. The diagnostic value of lumbar puncture (LP) was first recognized and described by Quincke in 1891.

Contraindication for lumbar puncture (1) Local sepsis at the site of the LP; (2) Suspected raised intracranial pressure; (3) Thrombocytopenia or other bleeding diathesis (platelet count < 20,000/mm^3, INR > 1.4), (anticoagulation therapy should be avoided for at least 2 hours following LP) and (4) In a critically ill patient, LP is withheld temporarily as the procedure may lead to cardiorespiratory compromise. Neuroimaging prior to LP should be considered in immunocompromised state, suspicion of mass lesion, stroke, focal infection, papilledema, altered level of consciousness and focal neurological deficit.

Cerebrospinal Fluid Gross Examination

Opening pressure Opening pressure is measured using a manometer. Normal CSF pressure varies with age. It ranges from 10 mm H$_2$O to 100 mm H$_2$O in young children, 60–200 mm H$_2$O after 8 years of age. In obese adult it ranges from 60 mm H$_2$O to 250 mm H$_2$O. Minor fluctuation in physiological ICP occurs with heartbeat (2–5 mm H$_2$O), breathing (4–10 mm H$_2$O) and Valsalva maneuver. Opening pressure above 250 mm of H$_2$O is diagnostic of intracranial hypertension. Raised intracranial pressure is noted in various pathological states, including meningoencephalitis, brain abscess, brain tumor, intracranial bleed, idiopathic intracranial hypertension.

Appearance (Clear, turbid, xanthochromic) Normal CSF is crystal clear like water. Elevated white blood cell (WBC) count (> 200/mm^3) or red blood cell (RBC) count (> 400/mm^3) will cause CSF to appear turbid. Xanthochromia (yellowish CSF) is caused by lysis of RBCs (due to hemoglobin breakdown products), hyperbillirubinemia or elevated CSF protein (> 150 mg/dL). CSF may appear orange in hypercarotenemia and treatment with rifampicin. Brown discoloration of CSF may occur in meningeal melanomatosis.

Cerebrospinal Fluid Cytology

In children and adult normal CSF may contain up to 5 WBC/mm^3 (70% lymphocytes, 30% monocytes), while neonate may have up to 19 WBC/mm^3. CSF WBC count is increased in meningitis, encephalitis, central nervous system (CNS) demyelinating disorders, immunological disorders and malignancy. CSF lymphocytosis is seen in viral, fungal and tubercular infection of CNS, although in earlier stage of illness a predominance of polymorphonuclear leukocytes (PMNs) may be seen. CNS demyelinating disorders, GBS, brain and spinal cord tumor, collagen vascular diseases and chemical meningitis may also cause CSF lymphocytosis. In bacterial meningitis predominant CSF cells are PMNs, however, approximately 10% of bacterial meningitis cases will show a lymphocytic predominance (defined as > 50% lymphocytes or monocytes), especially early in the clinical course and when there are fewer than 1,000 WBCs/mm^3.

Traumatic tap results in an artificial increase in WBC count by approximately one WBC for every 700 RBCs in the CSF. In patients with an abnormal hemogram, the direct calculation is corrected by the observed plasma ratio: Predicted WBC (CSF) = RBC (CSF) × [WBC (plasma)/RBC (plasma)]. If traumatic tap occurs, CSF is collected in three consecutive tubes and cell count is measured. If the number of RBCs is relatively constant, then it is assumed that the blood is caused by an intracranial hemorrhage. A falling count suggests traumatic tap. This three-tube method, however, is not always reliable. Neoplastic cells, eosinophils and plasma cells within the CSF are always considered abnormal.

Cerebrospinal Fluid Biochemistry

Glucose CSF glucose is approximately two-thirds of plasma glucose measured during the preceding 2–4 hours. CSF glucose levels generally do not go above 300 mg/dL. CSF glucose concentration below 40 mg/dL (hypoglycorrhachia) or a ratio of less than two-thirds of the plasma glucose level is considered abnormal. Bacterial meningitis can cause decreased CSF glucose levels. A low CSF glucose level is uncommon in viral meningitis but has been reported in mumps, herpes simplex, and herpes zoster meningoencephalitis. Noninfectious conditions like meningeal carcinomatosis, sarcoidosis, chemical meningitis, hypoglycemia, and subarachnoid hemorrhage may cause lowered CSF glucose concentration.

Protein In normal infant and adults, CSF protein concentration in the ventricular compartment is (6–15 mg/dL), in the cistern magna 15–25 mg/dL, and 20–50 mg/dL in the lumbar sac. The CSF protein concentration is high (up to 150 mg/dL) in the neonate, the adult value is reached between 6 months and 12 months of age. Elevated CSF protein is seen in CNS infections, intracranial hemorrhage, Guillain-Barré syndrome, CNS demyelinating disorders, brain and spinal cord tumor, myxedema and status epilepticus. Protein concentration is spuriously elevated by the presence of RBCs in a traumatic tap situation. 1 mg/dL of protein is increased for every 1,000 RBCs/mm^3. This correction is only accurate if the same tube is used for the protein and cell counts. Very high CSF protein content may be observed in a spinal cord tumor, arachnoiditis,

and other reasons leading to complete spinal CSF obstruction. Low CSF protein levels can occur in conditions such as repeated LP or a chronic leak, in which CSF is lost at a higher than normal rate. Elevation of CSF immunoglobulin G (IgG), which normally represents approximately 10% of the total protein, is observed in subacute sclerosing panencephalitis (SSPE), postinfectious encephalomyelitis, and in some cases of multiple sclerosis. CSF oligoclonal bands are present in multiple sclerosis.

Other metabolites Cerebrospinal fluid lactate concentrations are elevated in patients with bacterial infections and in mitochondrial encephalopathies. CSF hypoglycorrhachia and low lactate value in the absence of systemic hypoglycemia is virtually diagnostic of glucose transporter type 1 (GLUT 1) deficiency syndrome. Early onset nonketotic hyperglycinemia shows elevated CSF glycine levels; certain type of intracranial tumors may lead to elevated alpha (α)-fetoprotein, human chorionic gonadotropin, polyamines and astroglial protein concentrations. CSF biogenic amines should be measured in suspected pediatric neurotransmitter disorders.

Cerebrospinal Fluid Examination for Microorganism

Gram stain permits a rapid and accurate identification of causative bacteria in 60–80 of untreated cases of bacterial meningitis. Yield of Gram stain depends on causative organism, and concentration of bacteria in CSF [colony forming units (CFU)]. Greater number of CFU ($> 10^5$ CFU/mL) increases the likelihood of getting positive results. Centrifuged samples should be used for staining. Acid fast staining should be done if tubercular meningitis is suspected. India ink preparation may show organism in approximately 50% cases of cryptococcal meningitis.

Cerebrospinal fluid culture on 5% sheep blood agar and enriched chocolate agar is gold standard for diagnosis of bacterial meningitis. The first 1–2 mL of CSF, even traumatic should be stained and cultured for organisms. Antibiotic treatment prior to LP decreases the sensitivity of culture.

Latex agglutination (LA) allows rapid detection of bacterial antigens in CSF. LA shows good sensitivity in detecting antigens of common meningeal pathogens, i.e., *Haemophilus influenzae* type B (78–100%), *Streptococcus pneumoniae* (67–100%), *Streptococcus agalactiae* (69–100%) and *Neisseria Meningitides* (50–93%). Some experts suggest using LA in cases of suspected bacterial meningitis if the initial Gram stain and bacterial culture are negative after 48 hours. Polymerase chain reaction (PCR) is rapid and sensitive test for diagnosis of viral meningoencephalitis. PCR has sensitivity of 95–100% for diagnosis of herpes simplex virus type 1 (HSV1), enterovirus, Epstein-Barr virus meningitis.

Complications of Lumbar Puncture

Lumbar puncture is a relatively safe procedure, but minor and rarely major complications may occur even when aseptic measures and good technique are used. Pain and paresthesias in the distribution of a lumbar nerve root resulting from contact with the needle during procedure may occur. (*Caution*—reposition the needle toward the midline). Permanent nerve injury is highly unlikely. Postprocedural headache: occurs in approximately 10–33% patients, may occur within 72 hours of procedure, it gets relieved with supine position. Rare complications include intrathecal infection, cerebral herniation, bleeding and formation of epidermoid tumors (which can be avoided by using spinal needle with proper fitting stylet).

In rare situations CSF may be obtained from ventricles, ventriculoperitoneal shunt and cistern. A reservoir (Ommaya) can be implanted in patients requiring repeated withdrawal of CSF or repeated intraventricular medications; this allows safer and more convenient access.

Subdural tap may be done as diagnostic/therapeutic tool for subdural collection (effusion or blood).

Ventricular Tap

A ventricular tap is indicated for the removal of CSF directly from lateral ventricle of a patient with hydrocephalus and open anterior fontanel, which shows life-threatening raised intracranial pressure not responding to conservative management. A patient with closed anterior fontanel requires surgical approach to reach ventricular system. The procedure carries significant risk of infection, hemorrhage and parenchymal brain damage.

NEUROPHYSIOLOGY

Neurons and muscle cells membrane have a stable resting membrane potential. During depolarization ion channels open up and movement of sodium (Na^+), potassium (K^+), and calcium (Ca^{2+}) occurs, generating action potentials. These signals are transmitted between neurons through synapses. The action potentials are recorded as waveforms in the laboratory.

Neurophysiologic tests have an important role in the diagnostic evaluation and management of the infant or child with neurological dysfunction. Commonly performed neurophysiological studies in pediatric patients include electroencephalography (EEG), and evoked responses [brainstem auditory evoked potentials, visual evoked response (BAEP, VER)], nerve conduction study (NCS) and electromyography (EMG). Other neurophysiological tests include polysomnography, somatosensory evoked potentials (SSEP) and electroretinography.

Electroencephalography

Electroencephalogram is the recording of the electrical activity from the cortical neurons recorded by amplifying voltage differences between specifically placed electrodes. EEG is recorded by applying electrodes on the scalp, cerebral cortex or inside the brain. Potential difference between the electrodes are amplified and recorded. Electrodes are named according to the underlying area of the brain, e.g., frontal (F), frontopolar (Fp), temporal (T), occipital (O), parietal (P) and central (C) **(Fig. 1)**. All electrodes on right side are assigned even numbers and left side odd numbers. A particular combination of placement of electrodes is called a *montage*. The EEG recording is made up of a number of channels. In a single
Figure 1 Numbering and placement of electrodes
Abbreviations: Fp, frontopolar; F, frontal; T, temporal; O, occipital; P, parietal; C, central; z indicates midline electrode.

recording multiple montages are used. The two common montages used are the bipolar montage and the referential montage.

Electroencephalographic waveforms These are classified according to their frequencies, shape and site. These usual EEG waveforms are broken down into the following ranges:

- Delta (δ) below 3.5/s
- Theta (θ) 4–7.5/s
- Alpha (α) 8–13/s
- Beta (β) 14–30/s

These waveforms are influenced by many factors, including age, state of alertness (awake or sleep), eye closure, drugs and pathological states. Normal EEG has a wide range of variation in different age groups. Proper knowledge of normal evolution and maturation of various sleep and awake rhythm is important for EEG interpretation. The posterior rhythm attains α range of 8 Hz by 3 years of age **(Fig. 2)**. Abnormalities of waveform include spikes, sharp waves and slow waves. Certain EEG features are diagnostic for particular epilepsy syndromes, e.g., 3 Hz spike wave discharge in childhood absence epilepsy **(Fig. 3)**. Various activation procedures (hyperventilation, intermittent photic stimulation, sleep and sleep deprivation, etc.) are used to increase yield from EEG. During EEG, various artifacts (signals of noncerebral origin) are also recorded. Artifacts can be physiological or nonphysiological origin. It is also very important to identify and try to minimize artifacts.

Indications of Electroencephalography **(Box 1)**

- As an aid to clinical diagnosis of epilepsy
- Classification of seizure and epilepsy syndrome
- Diagnosis of nonconvulsive status epilepticus
- Diagnosis of certain diseases like SSPE
- Presurgical evaluation of epilepsy
- Determination of brain death.

BOX 1 **Important considerations for electroencephalography**

- Electroencephalography remains the principal investigation for children with epilepsy.
- Normal interictal EEG does not always rule out epilepsy, though repeated EEG and activation procedures may increase yield to 80%.
- An abnormal EEG does not always mean epilepsy, epileptiform EEG pattern occur in approximately 1–2% of patients with no history of epileptic seizures.
- Normal EEG variants may be confused for epileptiform discharges.
Figure 2 Posterior background alpha (α) rhythm in a 9-year-old boy with eye blink artifacts (arrows) in longitudinal bipolar montage
Figure 3 Electroencephalography (EEG) record of a 10-year-old boy with absence seizure showing classical generalized 3 Hz spike and wave discharges in longitudinal bipolar montage

Ambulatory EEG Continuous EEG is recorded during normal activities. It is useful in evaluation of seizure frequency and determination of nature of clinical event.

Video electroencephalography (VEEG) Video-EEG refers to continuous EEG recording with simultaneous video recording of the clinical manifestations. It is useful for differentiation of epileptic seizure from nonepileptic event and characterization of epileptic seizure. It has important role in presurgical localization of epileptogenic focus. It is expensive and long-term VEEG requires hospital admission.

Magnetoencephalography (MEG) Magnetoencephalography refers to mapping of brain activity by recording magnetic fields produced by electrical currents occurring naturally in the brain. Magnetic fields are less distorted than electric fields by the skull and scalp, which results in a better spatial resolution of the MEG. Indications of MEG for pediatric patients are detecting spontaneous epileptiform activities and mapping eloquent cortices of motor, sensory and language. Magnetic source imaging refers to the superimposition of magnetoencephalographic signals with magnetic resonance imaging (MRI) to improve spatial resolution compared with surface EEG.

Evoked Potentials

Evoked potential or evoked response refers to electrographic response of nervous system to variety of sensory stimuli. In clinical practice, commonly performed evoked responses are visual evoked potentials (VEPs; flash and checkerboard types), BAEPs and short latency SSEPs. Sensory stimulus leads to generation of sequence of waves, the latencies and amplitudes of waves represent conduction and processing of sensory information in peripheral and central pathway.

Brainstem Auditory Evoked Potentials

Brainstem auditory evoked potentials assess integrity and functional status of both the peripheral (acoustic nerve) and central auditory pathways in the brainstem. BAEPs comprise of five or more positive waves occurring within 10 ms of auditory stimulus **(Fig. 4)**. Different waves are generated at different sites along the auditory pathway **(Table 1)**. Peak and interpeak latencies are compared with normative data. BAEP matures to adult pattern over a period, from birth to 18–24 months of age. Various waves mature at different ages. In clinical practice BAEP is used for:

• Hearing assessment in infants, children and uncooperative patients
Figure 4 Normal brainstem auditory evoked potential (BAEP) of a 6-year-old boy at 60 dB. Sweep time 1 ms/div, sensitivity 0.2 mV/div

Table 1 Origin of various waves in brainstem auditory evoked potential (BAEP)

Wave I	Cochlear nerve
Wave II	Dorsal and ventral cochlear nucleus
Wave III	Superior olivary nucleus
Wave IV	Lateral lemniscus
Wave V	Inferior colliculus

• Patients with meningitis (for hearing loss)
• For the diagnosis of demyelinating diseases (MRI is more informative)
• Extramedullary and intramedullary brainstem tumors (MRI is more informative)
• Prognosis of comatose patients (metabolic or structural lesions)
• Suspected brain death.

Interpretation

• *Wave I:* Small amplitude, delayed or absent may suggest cochlear lesion
• *Wave V:* Small amplitude, delayed or absent may suggest upper brainstem lesion
• *Wave I–III inter-peak latency:* Prolongation may indicate lower brainstem lesion.
• *Wave III–V inter-peak latency:* Prolongation may indicate upper brainstem lesion.
• *Wave I–V inter-peak latency:* Prolongation may indicate whole brainstem lesion. Shortening of the interval with normal latency of wave V indicate cochlear involvement.

For hearing evaluation in children, the earphones should be comfortably placed on the child's ears. For neonatal screening, 70 dB hearing level clicks are presented at 11 Hz. Hearing is then more closely assessed using 30 dB clicks presented at the rate of 61 Hz. Any infant without a response at 30 dB should be followed up at 3 months.

Somatosensory Evoked Potential

Short latency somatosensory evoked potential refers to electric potential generated by large diameter sensory fibers in the peripheral and CNS in response to electrical stimulus. Commonly performed SEPs are median, peroneal and posterior tibial SEP. SSEP is helpful in evaluation of myelitis, myoclonus and prognosis of comatose patient.

Visual Evoked Potential

Visual evoked potentials **(Fig. 5)** test the function of visual pathway from retina to the occipital cortex. VEP can be elicited by flash of lights or by checker board. Peak latency and amplitudes of the waves are measured. On flash VEP latency, amplitude and morphology of adult VEP are achieved by 6 months of age. VEP is helpful in diagnosis of prechiasmatic, chiasmatic and postchiasmatic lesions. Patterned stimuli VEP can be recorded from birth and may be used as a measure for assessment of visual acuity in preverbal child. Abnormal VEP can be recorded in demyelinating disorders, tumors, neurodegenerative disorders and developmental disability.

Electroretinography

Electroretinography (ERG) is a test to measure the electrical response of retina (rods and cones) in response to light stimuli (flash of lights or patterned stimuli). By 1 year of age ERG amplitudes are comparable to adult value. ERG is helpful in diagnosis of various
Figure 5 Visual evoked potential (VEP) showing N70, p100, N155 waveforms. Sweep time 30 ms/div, sensitivity 5 mV/div

diseases of visual system (retinitis pigmentosa, photoreceptor dystrophy, Leber's hereditary amaurosis and retinal trauma).

Polysomnography

Polysomnography is useful in evaluation of various sleep disorders, i.e., sleep apnea, narcolepsy, periodic limb movement disorder and parasomnias. The nocturnal polysomnography measures various biophysiological parameters during sleep, i.e., EEG (2–4 channel), eye movements (electro-oculogram), chin and leg electromyogram, respiratory efforts (thoracic and abdominal), heart rhythm (ECG) and oxygen saturation. After completion of test scoring is done for sleep and sleep related events.

Nerve Conduction Studies

Nerve conduction study is a diagnostic modality, used to evaluate function (conduction of electrical impulses) of motor and sensory nerves in response to electrical stimulation of nerve. Standard NCS typically include motor nerve conduction, sensory nerve conduction, F waves and H reflexes. Amplitude, latency and conduction velocity of generated action potentials are analyzed. Motor and sensory nerve conduction velocities in the neonatal period are about half of adult value; with steep conduction increase during the 1st year of life, adult values are reached around 4 years of age. In demyelinating disorders of nerve, distal latency is increased and velocity decreases, whereas in axonal injury amplitude decreases. Repetitive nerve stimulation test is done for disorder of neuromuscular transmission.

Electromyography

Electromyography is a diagnostic procedure to assess electrical activity produced by skeletal muscles. Two kinds of EMG are done:

surface EMG or intramuscular (needle) EMG. In needle EMG, an EMG needle is inserted in muscle belly and insertional activity, spontaneous activity (fasciculation, fibrillations, end plate noise and myotonic discharges) and motor unit action potential are analyzed. It aids in diagnosis of diseases of nerve, neuromuscular junction and muscle. EMG leads to transient rise in serum creatine phosphokinase (CPK) levels.

IN A NUTSHELL

1. Properly interpreted CSF examination is a key tool in the diagnosis of a variety of diseases.
2. Electroencephalography is the most useful laboratory investigation in patients with epileptic seizure.
3. Knowledge of normal maturation pattern of EEG waveforms and normal variants is essential for proper interpretation of EEG.
4. Evoked potentials assess the integrity or functional status of both the peripheral and the central (brainstem, subcortical and cortical) pathways in response to various stimuli.
5. Brainstem auditory evoked potential along with otoacoustic emission (OAE) is an effective screening tool in evaluation of hearing in newborn with high sensitivity (100%) and specificity (96–98%).
6. Polysomnography is important diagnostic tool in sleep medicine.

Chapter 42.3
Neuroimaging
Atin Kumar, Jyoti Kumar

Advances in modern imaging techniques have greatly improved our understanding of the pathology of central nervous system in children. Various imaging techniques now available can provide us with both structural and functional information.

Ultrasonography (US) is usually the first imaging modality used in newborns and infants, as it is widely available, can be done at bedside and does not involve ionizing radiation. Magnetic resonance imaging (MRI) and computed tomography (CT) have greatly evolved over the years to give us high-quality images. The advent of multidetector CT scan has greatly reduced the imaging time of the scan, markedly reducing the incidence of motion artifacts. Near isotropic data obtained on multidetector CT gives us excellent multiplanar reconstructions. However, CT involves use of ionizing radiation. MRI, on the other hand, gives superb soft tissue resolution without the use of ionizing radiation. Advances in MR hardware and software have also improved the speed of MR scanning. However, motion artifacts may still be a problem on MR images, especially if the patient is not well sedated. Imaging parameters for acquisition of optimal images in the pediatric population varies from those used in adults, especially newborns and infants, because of the varying chemical composition of developing brain.

Functional imaging techniques like magnetic resonance spectroscopy (MRS), functional MRI (fMRI), nuclear imaging techniques like positron emission tomography (PET) and single photon emission CT (SPECT) can allow us to study neural function across the brain and provide a map of neural activity. Functional neuroimaging techniques can depict the activity of brain during cognitive tasks, thus enabling neuroscientists to study differences in pediatric and adult population that can further help to design treatments tailored to patients in the pediatric age group.

In this chapter we will discuss about the basics of the various neuroimaging techniques and practical aspects for interpreting them. Detailed discussion about imaging appearances of various pathologies will be discussed within each respective chapter in the book.

CRANIAL SONOGRAPHY

The presence of an open anterior fontanel during the 1st year of life provides a window for ultrasound evaluation of the brain **(Figs 1A to F)**. Progressive improvements in software technology, and probe designs have improved image quality and resolution of both anatomy and pathology on ultrasound. The addition of Doppler imaging has further provided an impetus to the role of ultrasound in evaluation of the pathological processes involving the brain. Ultrasound does not use ionizing radiation and causes minimal disturbance to a sick neonate. The most extensive use of cranial sonography is for diagnosis and monitoring of brain injury in the premature infant at high-risk for intracranial hemorrhage and hypoxic ischemic injury.

However, there are several limitations to evaluation of the brain by ultrasound. Transfontanel imaging is usually done in the coronal and sagittal planes which is different from the axial images we routinely see on CT or MRI. It is an operator-dependent technique with limited views of the posterior fossa and convexities. Fresh intraventricular hemorrhage may not be immediately identified on US unless it clots. It is less sensitive for subarachnoid and surface hemorrhage than CT.

Ultrasonography is sensitive to ventricular dilatation and minor degrees of ventricular asymmetry. Ventricular dilatation can result from a variety of causes, intraventricular hemorrhage being a common cause in neonates. This may either arrest, regress to normal or progress to hydrocephalus. Ventricular dilatation may also be a result of *ex-vacuo* dilatation secondary to volume loss due to global insult. Ultrasound is a useful modality to monitor changes in ventricular size, to assess the placement of shunt tip and can also be used for ventricular or lumbar taps as a temporizing measure before shunt placement.

The ventricle to hemispheric ratio is calculated from measurements on both sides in the axial plane. Normal values are between 0.2 and 0.33. Slightly higher ratios have been found in preterm infants (0.32–0.36); term values being achieved at about 36 weeks of gestation.

Doppler ultrasound consisting of pulse wave, continuous wave, and color flow Doppler imaging can be used to assess blood flow in many pathological states including hypoxic ischemic damage, congenital malformations and to assess the need for shunt placement in hydrocephalus **(Figs 2A to C)**.

COMPUTED TOMOGRAPHY

Since radiation dose is always an issue in pediatric patients, choice of CT as an imaging modality must be made with caution. In comparison with CT, MRI has much superior soft tissue resolution with greater sensitivity for acute ischemic damage, assessing myelination patterns and white matter disorders. The advantages of CT include its wide availability and reproducibility. Also, the scan is not as operator independent as ultrasound. Major applications of CT include evaluation of acute cerebral trauma, pathology involving skull bones and orbits, temporal bone and paranasal sinus pathology, follow-up of CSF shunt, evaluation of subarachnoid hemorrhage and craniosynostosis **(Fig. 3)**.

On a CT scan the structures which attenuate the radiation the least appear dark (hypodense) and which attenuate the radiation the most appear bright (hyperdense). The intermediate structures show the varying shades of gray. Hence, air appears absolutely hypodense followed by fat which is slightly more attenuating (more gray than air), followed by liquid (CSF in brain). The soft tissues show higher attenuation than fluids. The bone, calcifications and metallic densities appear the brightest and are maximum hyperdense. The bleeds also appear hyperdense in acute stage. Contrast enhancement is also seen as hyperdense lesions. The attenuation is quantitatively measured in terms of Housesfield units (HU). Thus the HU value is least for air (around –900), more for fat (–90 to –10), about 0–20 for fluids, 20–60 for soft tissues, 100–200 for contrast enhancements and 200–800 for calcifications, bone and metallic structures.

Axial images on CT are obtained parallel to the canthomeatal line using a slice thickness of 2.5–5 mm. To reduce the radiation dose, coronal images may be obtained by reconstructing the axial images. With the advent of multidetector CT, we can obtain nearly isotropic data for high quality multiplanar reconstruction. In cases of craniosynostosis, scans of 3 mm or lesser thickness should be obtained and three dimensional reformations of the bones can then be obtained by using specialized software to assess suture patency.

Contrast medium is administered when looking for infectious, neoplastic or vascular pathology **(Fig. 4)**. Contrast is administered in a dose of 2 mL/kg of body weight. CT angiogram (CTA) may be

done for vascular anomalies like arteriovenous malformations or aneurysms.

MAGNETIC RESONANCE IMAGING

Magnetic resonance imaging provides multiplanar imaging with excellent spatial and contrast resolution without repositioning the patient or the machine. Its advantages over CT scan include no harmful effects of ionizing radiation, better resolution and no bone interference with soft-tissue resolution. Its advantages over ultrasound include better resolution and no limitation of timing as it can be done even after fontanel closure contrast from ultrasound which requires acoustic window for cranial examination and hence possible before fontanel closure only.

Figure 4 Axial contrast enhanced CT image of the brain at the level of basal cisterns shows densely enhancing exudates in all basal cisterns in tubercular meningitis

The patient is positioned within an MRI scanner wherein a strong magnetic field is created around the area to be imaged. The process requires a strong and uniform magnetic field. Field strength of magnet is measured in Tesla. It ranges from 0.2 to 7 Tesla with 1.5 T and 3 T being the most commonly clinically used magnets. Orientation of the image is controlled by varying the main magnetic field using gradient coils. Radiofrequency pulses are used to obtain high resolution images from the body.

The hydrogen nuclei (protons) present in various tissues of the body are used to generate signals from the body which are detected and processed by the equipment to generate useful images. The noise produced during MR examination is caused by switching on and off of the coils used to generate signal. The signal obtained from different tissues varies depending upon various factors—the density of protons within that particular tissue, the mobility of protons within the molecular lattice (referred to as T1 relaxation), the effect of local magnetic fields produced by magnetic nuclei within the tissue (referred to as T2 relaxation) and susceptibility effects from paramagnetic ions (e.g., from Fe ions in bleeds) on local magnetic fields within tissue (referred to as T2* relaxation).

The MRI uses different programmed imaging sequences like spin echo (SE), fast spin echo (FSE), gradient-recalled echo (GRE) and inversion recovery (IR) to obtain images from the tissues. These sequences use the above-mentioned factors in varying weightage to generate different signals from different tissues. Hence, all of these, i.e., SE, FSE, GRE and IR sequences can be used to produce a T1-weighted (T1W) image or a T2-weighted (T2W) image.

The production of a T1W or a T2W image is controlled by two main parameters—time to echo (TE) and time for relaxation (TR). Keeping a short TE (in the range of 12–25 s) and short TR (in the range of 450–600 s) produces T1W image whereas a long TE (in the range of 100–120 ms) and a long TR (in the range of 3,500–4,500 ms) produces a T2W image. A short TE and a long TR produces a proton density (PD) image which is solely dependent on density of hydrogen nuclei within the tissue.

T1-weighted image predominantly uses the T1 relaxation properties of tissues to differentiate them from each other. Herein tissues with short T1 relaxation times like fat and intracellular and extracellular methemoglobin (seen in hemorrhage) produce a high

signal intensity (bright or hyperintense) whereas tissues with long T1 relaxation times like fluid (CSF in brain), soft tissues, muscle, deoxyhemoglobin and hemosiderin produce low signal intensity (dark or hypointense). As a general rule most of the tissues and pathologies appear hypointense or isointense on T1W images. It is easier to remember the exceptions, i.e., tissues which show hyperintense signal on T1W image—fat, subacute hemorrhage (containing methemoglobin), high protein content fluid (within some cysts), melanin, slow flowing blood in vessels, calcification (sometimes) and contrast material like gadolinium. On a T1W image of the brain in a child when myelination is complete (above 2 years of age) the gray matter appears gray and white matter appears white (hyperintense) **(Fig. 5A)**.

T1-weighted image is useful for anatomy and for postcontrast examination. It is generally not used for detection of pathologies but is rather used to characterize and localize the pathologies detected on a T2W image. One important use of T1W image is after administration of MR contrast agent. Postcontrast T1W images are good for visualization of blood vessels and also shows enhancement of lesions with blood brain barrier (BBB) breach like infections, tumors, subacute stages of infarct.

T2-weighted image predominantly uses the T2 relaxation properties of tissues to produce contrast resolution between them. The tissues with long T2 relaxation times like fluid (CSF in brain), edema—vasogenic or cytotoxic (seen with most pathologies including infarcts, demyelination, tumors, etc.) and extracellular methemoglobin (in hemorrhage) appear hyperintense whereas tissues with short T2 relaxation like cortical bone, deoxyhemoglobin, hemosiderin and muscle appear hypointense. Hence, as a general rule most of the tissues and pathologies appear hyperintense on T2W images. The only exceptions which appear isointense or hypointense on T2W image include air, calcification, early and late hemorrhage (containing deoxyhemoglobin or hemosiderin), melanin, iron or other mineral deposition, high protein content fluid and fast flowing blood in vessels (called as flow voids). On a T2W image of the brain in a child when myelination is complete (above 2 years of age) the gray matter appears gray and white matter appears dark (hypointense) **(Fig. 5B)**.

Inversion recovery sequences are typically used to selectively eliminate or nullify signal from a particular tissue. The most commonly used IR sequence is fluid attenuated inversion recovery (FLAIR) which as the name suggests nullifies the signal from fluid (CSF in brain) **(Fig. 5C)**. FLAIR has got T2W which means the CSF which should have been hyperintense now gets suppressed and appears hypointense. But the other pathologies within the brain parenchyma which produce edema in interstitium still appear bright or hyperintense. Hence, this sequence is more sensitive than simple T2W image to detect subtle hyperintense signal changes especially in regions adjacent to CSF containing ventricles and sulcal spaces **(Figs 6A to C)**.

Gradient-recalled echo sequences (*T2 star or T2**) produce images in which the signal is susceptible to presence of paramagnetic substances like iron or calcium. These images are hence best used for identification of bleeds (containing iron) and calcifications (containing calcium). In general GRE sequences are faster in terms of acquisition time as compared to SE sequences.

Susceptibility-weighted imaging (SWI) is another type of technique which uses sequences which enhance the magnetic inhomogeneities of iron and calcium and produce marked hypointense signal (blooming) in areas containing these ions. These sequences are more sensitive than the routine T2* sequences (e.g., FLASH) for detection of bleeds and calcifications **(Figs 7A to C)**. Another advantage of SWI is that bleed and calcifications can be differentiated from each other based on evaluation of various components of SWI which is not possible on over T2* FLASH images.

Diffusion-weighted imaging (DWI) is a technique that uses MRI to measure the diffusion of water through tissues. Diffusion refers to the random (Brownian) motion of water molecules within a tissue which is dependent upon structural and physiologic factors within that tissue. If there is unrestricted diffusion then the chances of motion are equal in all directions—referred to as isotropic diffusion. However, if the structural factors allow diffusion primarily in one direction while restricting the movement in other perpendicular directions then it is referred to as anisotropic diffusion. The prime example of this is white matter fibers because its component axon allows water diffusion only along the long axis and hence in the direction of the tract fiber. If there is restriction of diffusion of water molecules within the tissue then MRI detects it as restricted diffusion. This occurs in the setting of intracellular
Figures 5A to C (A) T1W; (B) T2W and (C) FLAIR. Axial MR images of the brain at the level of basal ganglia and lateral ventricles. The gray matter is gray on T1W, T2W and FLAIR images but the white matter is white on T1W image and dark on T2W and FLAIR images. The CSF within the ventricles is hypointense on T1W image, hyperintense on T2W image and gets suppressed (becomes hypointense) on the FLAIR image
Figures 6A to C (A) T2W; (B) FLAIR and (C) Postcontrast T1W. Axial MR images of the brain in a child of disseminated tuberculomas. The multiple lesions with hyperintense edema are seen on T2W image but are better appreciated on the FLAIR image. The lesions show ring enhancement on the postcontrast T1W image
Figures 7A to C (A) T1W; (B) T2W and (C) SWI. Axial MR images of the brain show bilateral parenchymal bleeds appearing hyperintense on T1W and heterogenous on T2W images. *Note:* The *blooming* seen on SWI images. These were secondary to venous sinus thrombosis

cytotoxic edema. The conditions which show restricted diffusion on DWI include infarcts, hypoxic ischemic encephalopathy (HIE), abscesses, certain high-grade neoplasms and some acute demyelinating plaques. Diffusion restriction is best seen in acute phase and gradually diminishes with time. Hence, in acute pathologies, timing of examination from initiation of symptoms is important for correct interpretation of DWI images. For example in acute infarct **(Figs 8A to C)**, the diffusion restriction can be seen as early as within an hour of insult (even before changes are seen on conventional T1W and T2W images), show peak restriction by 48–72 hours and then start to decline to become almost normal by 7–10 days.

Diffusion tensor imaging (DTI) is an advanced diffusion technique which acquires diffusion characteristics of tissues in multiple directions. Data generated out of this result in not just quantification of restriction of diffusion but also direction of restriction. DTI images are used to evaluate white matter tracts. If there is loss of anisotropy in a white matter tract it signifies destruction of its anatomic structure. Tractography is the technique used to depict the entire course of a white matter tract **(Fig. 9)**. It has been used to

map white matter tracts in brain and look for any involvement by disease processes like HIE, infarcts and tumors.

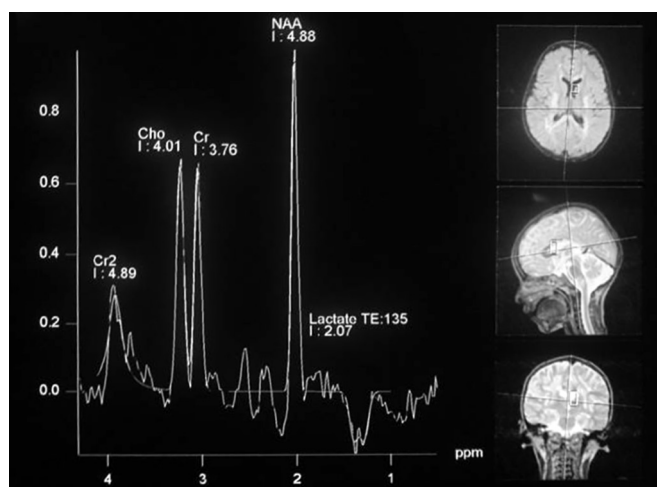
Magnetic resonance spectroscopy is an in vivo technique to demonstrate and quantify certain brain metabolites noninvasively. The technique used most commonly in brain studies is proton MRS. The metabolites detected include N-acetylaspartate (NAA) which resonates at a frequency of 2.0 ppm and is a marker of intact neuronal tissue, creatine (Cr) which resonates at 3.0 ppm and is a marker of brain energy metabolism and choline (Ch) which resonates at 3.2 ppm and is a marker of cell membrane and represents cellular density. These three metabolites are consistently seen in a brain spectrum **(Fig. 10)**. NAA level decreases in most diseases causing neuronal or axonal loss and therefore is nonspecific. However, the extent of decrease can quantify the extent of the disease process. NAA levels are increased in Canavan disease and are diagnostic of this condition. It occurs because of deficiency of NAA in Canavan disease, an enzyme which causes breakdown of NAA. Creatine levels are abnormal in diseases of Cr synthesis. Choline levels are high in conditions of excessive cell turnover including proliferative tumors, leukodystrophies,
Figures 8A to C (A) T2W; (B) 1,000 DWI image and (C) ADC map. Axial MR images of the brain show an acute infarct in right periventricular region which is hyperintense on T2W image, hyperintense on DWI image and hypointense on corresponding ADC map
Figure 9 Tractography of brain white matter tracts acquired by DTI shows various white matter tracts coded by colors. Craniocaudal are blue, right to left are red and anteroposterior are green


Figure 10 Magnetic resonance spectroscopy (MRS) of the brain showing NAA peak at 2.0 ppm, creatine peak at 3.02 ppm and choline peak at 3.2 ppm. Note also the inverted lactate doublet peak at 1.3 ppm. This was a case of Leigh's disease

demyelination and gliosis. The other metabolites which may be seen include lactate (Lac) which shows a doublet peak at 1.33 ppm and represents anaerobic metabolism. Lac peaks are often seen in tumors with necrosis, mitochondrial disorders and HIE. Lipid (Lip) resonates between 0.9 ppm and 1.3 ppm and is a marker of breakdown of cell membrane and release of fatty acids. Lipid peaks are seen in aggressive tumors and infections. Branched chain amino acids show peak at 0.9 ppm and are elevated in Maple syrup urine disease. Myo-inositol peak is seen at 3.6 ppm and is elevated in glial-based tumors and adrenoleukodystrophy.

Rather than absolute values of individual peaks, it is often the ratios between various metabolites which are used as markers to quantify the severity of disease. The commonly used ratios include Cho/NAA, Ch/Cr and Lac/NAA.

Functional MRI (*fMRI*) is a technique which assesses cortical neuronal activity by indirect method of measuring regional cerebral vascular response. The principle used here is that changes in oxygen saturation of the hemoglobin in blood produces a small change in local MR signal which is known as the blood oxygenation level—dependent (BOLD) effect. The deoxyhemoglobin being paramagnetic in nature produces decreased signal due to local inhomogeneities in magnetic field. However, in response to increased demand (as occurs in stimulation of cortical area), there occurs transient increase in regional cerebral blood flow with increased inflow of oxygenated hemoglobin. This is much more than the cerebral metabolic rate of oxygen and hence there is decreased extraction of oxygen from hemoglobin. This leads to displacement of deoxyhemoglobin by oxygenated hemoglobin which results in increased signal (as deoxyhemoglobin causes decrease in signal). In practical aspects, when a task is given to the patient, the cortical area of brain involved in executing that task shows increased signal on BOLD maps and hence can be mapped. In pediatric population patient compliance remains a practical issue. fMRI has been used in pediatrics for presurgical mapping for epilepsy or tumor surgery and also for studies of cognition and language networks.

Magnetic resonance angiography (MRA) is a group of techniques used to image blood vessels by MRI. It can be arteriography or venography depending upon whether arteries or veins are imaged. The methods used to obtain images can involve flow dependent techniques like *time-of-flight* (TOF) and phase contrast (PC) angiography. TOF is the most commonly used method in brain angiographies **(Fig. 11)**. It gives excellent images without the use of contrast material. But the disadvantages include a long time of
Figure 11 Time-of-flight (TOF) MR angiography of the intracranial arteries (AP projection) shows the major vessels constituting the circle of Willis

Figure 13 Postcontrast T1W axial magnetic resonance (MR) image shows abnormal enhancement (hyperintensity) along the basal cisterns and sylvian fissures consistent with meningitis

acquisition (ranging from 5 min to 15 min) and certain in-plane flow artifacts. MR arteriography is indicated in evaluation of stroke, aneurysms, arteriovenous malformations and Moyamoya disease. MR venography is indicated in suspected cases of venous sinus or cortical venous thrombosis **(Figs 12A and B)**.

Contrast-enhanced MRI can be obtained after administration of intravenous contrast. The most commonly used MR contrast agents are gadolinium based compounds. The indications for usage of contrast remain same as discussed in CT section above and include acute inflammations [infections or acute disseminated encephalomyelitis (ADEM)], tumors, specific white matter disorders like Alexander's disease and adrenoleukodystrophy and for suspected vascular anomalies. Contrast may also be used to perform MRA. Generally T1W images are used to detect contrast enhancements **(Fig. 13)**. The potential contraindications for giving gadolinium contrast agents include patients with acute or chronic severe renal insufficiency (glomerular filtration rate less than 30 mL/min/1.73 m^2) who have a risk of developing complication of nephrogenic systemic fibrosis (NSF). However,

per se the gadolinium agents are not nephrotoxic and may be used in mild decreased renal function wherein CT contrast agents are contraindicated.

The *contraindications for MRI* include electronic devices implanted within body like cardiac pacemaker and cochlear implants and metallic devices which are non-MR compatible like aneurysm clips, metallic stents, metallic coils, orthopedic implants, bullet fragments, etc.

NORMAL MYELINATION

The white matter is unmyelinated to start with. The process of myelination starts at fifth fetal month and continues till 2 years of age. Myelination progresses in a systematic manner from caudal to cephalad, from central to peripheral, from dorsal to ventral and from posterior to anterior. Hence, brainstem and cerebellum myelinate before cerebrum, basal ganglia and thalamus myelinate before deep white matter, posterior limb of internal capsule (PLIC) myelinates before the anterior limb of internal capsule (ALIC),
Figures 12A and B (A) Magnetic resonance (MR) venography of the intracranial venous system AP and (B) lateral views shows the major sinuses and cortical veins

splenium of corpus callosum myelinates before the genu and corona radiate myelinates before the subcortical region.

Magnetic resonance imaging is very useful in depicting the myelination process. Unmyelinated white matter due to high water content appears dark on a T1W and bright on a T2W image **(Figs 14A to F)**. When myelination occurs, there is decrease in water content and increase in lipid (or fat) content within the white matter. Hence, it starts to appear bright or hyperintense on T1W image and dark or hypointense on T2W image. It is important to remember here that the changes of myelination are depicted on MRI first on T1W image and after a time gap on T2W image. Hence, a structure which gets myelinated will appear hyperintense on T1W image initially and will become hypointense on T2W image only after a time gap ranging from few weeks to months. Most of the structures show complete myelination by 6 months on a T1W image but take up to 2 years to appear myelinated on a T2W image. So the process of myelination is better appreciated on a T1W image in the first 6 months and on a T2W image after 6 months **(Table 1)**.

Hence broadly the myelination on T2W image lags T1W image by about 2–3 months. The last associative area to mature is peritrigonal region (at the tips of occipital horns of lateral ventricles). This area shows persistent T2/FLAIR hyperintensity in ages up to 3 years. Abnormal hyperintense signal persisting beyond 3 years of age may represent changes of hypoxic ischemic encephalopathy especially if associated with volume loss.

The adult pattern of MR images on T1W and T2W are hence obtained at around 2 years of age **(Figs 15A to F)**. At this time onwards, on a T1W image the gray matter appears gray and the white matter appears white whereas on a T2W image the gray matter appears gray but the white matter appears dark.

POSITRON EMISSION TOMOGRAPHY

Positron emission tomography is a molecular imaging technique which generates maps of distribution of positron-emitting-radioisotope-labelled biomolecules in living body. The most common clinically used compound is (F-18) fluorodeoxyglucose (FDG) which maps the glucose metabolism in brain tissue. It thus detects pathological changes earlier than structural imaging techniques like CT and MRI. The images of PET are fused with structural images produced by CT (PET-CT) or MRI (PET-MRI). Hence, the functional changes shown by increased or decreased uptake of FDG are superimposed upon the anatomical images and
Figures 14A to F (A to C) Axial T1W and (D to F) corresponding T2W magnetic resonance (MR) images of the brain of a normal term neonate. The structures myelinated till now like posterior putamen, ventrolateral thalamus, posterior limb of internal capsule and perirolandic centrum semiovale show hyperintense signal on T1W and hypointense signal on T2W images. The rest of the unmyelinated deep and subcortical white matter shows hypointense signal on T1W and hyperintense signal on T2W images

Table 1 Normal myelination pattern

Age	T1W image	T2W image

The brain at this time shows adult pattern of myelination with complete white matter including that of both limbs of internal capsule and entire corpus callosum showing hyperintense signal on T1W and hypointense signal on T2W images. Note the gray matter appears gray on both T1W and T2W images

can be mapped to the involved area. With wider availability of PET MR, it is now slowly replacing PET-CT with advantage of decreased radiation exposure.

Fluorodeoxyglucose positron emission tomography (FDG PET) has been widely used in pediatric temporal lobe epilepsy especially mesial temporal sclerosis. It shows hypometabolism during the interictal stage and hypermetabolism during seizures. It also has been shown to have a role in extratemporal seizures wherein cortical foci of hypometabolism may be detected in interictal period. These areas may not be showing any structural changes on CT or MRI. FDG PET also has a proven role in assessing brain tumors. It helps to show the most metabolically

active parts of tumors and hence can help in choosing the part to biopsy or can help in surgical resection. It may also be used to differentiate between residual/recurrent tumor and radiation induced changes.

IN A NUTSHELL

1. The chief neuroimaging modalities in children include ultrasound, CT and MRI.
2. Ultrasound is the initial imaging modality used for evaluation of neonatal and infant brain.
3. Ultrasound is useful to detect intracranial hemorrhage and ventricular dilatation.
4. CT scan is easily available, cheaper and takes less time to perform as compared to MRI but has the risk of ionizing radiation and provides much lesser information.
5. MRI is the procedure of choice for detailed evaluation; It has multiplanar imaging capability combined with excellent contrast resolution and does not have any radiation issues.
6. Disadvantages of MRI include high cost, limited availability and increased time for imaging requiring sedation and/or anesthesia.
7. The advanced MRI techniques including MRS, DWI and fMRI have shown promise in making it a functional study combined with structural imaging.

Chapter 42.4
Neural Tube Defects and Spinal Cord Malformations
Sujata Kanhere

Neural tube defects (NTDs) and associated spinal cord malformations are the most common types of central nervous system congenital anomalies. NTDs are classified as primary defects and secondary defects. Primary NTDs which account for the majority (95%) are caused by failure of spontaneous closure of the neural tube, between the 3rd and 4th week of gestation. Secondary defects (5%) occur later, once the neural tube closes.

Neural tube defects consist of a wide range of malformations along the neuraxis. The common NTDs are spina bifida occulta, meningocele, meningomyelocele (MMC), anencephaly and encephalocele. Other NTDs and malformations of the spine include dermal sinus, craniorachischisis, lipoma involving conus medullaris or filum terminale, tethered cord, syringomelia, diastematomyelia, caudal regression syndrome and iniencephaly.

Neural tube defects affecting the spinal cord are collectively called spina bifida. These defects may be apparent as meningocele or MMC or inapparent (spina bifida occulta). Some of these conditions are benign, some are treatable but often the prognosis is poor and the handicap is severe. Other malformations or anomalies may also be present along with NTDs. The impact of the condition goes beyond the physical disability and psychological effects for the child to affect the entire family in terms of financial and social implications.

Neural tube defects are a result of genetic and environmental factors. Recent advances have led to strategies for prevention of NTDs such as periconceptional folic acid ingestion by women in child bearing age group, which have reduced the occurrence of NTDs by 70% and thus are important for every pediatrician to know. Equally important in prevention is prenatal screening during pregnancy as well as the role of genetic counseling for future pregnancies.

EPIDEMIOLOGY

The incidence of NTDs is 1.5–2.5/1,000 live births worldwide. Every year 3 lakh babies are born with NTDs globally. The incidence varies in different parts of the world and different regions within countries. In United States of America, incidence is 1/1,000 births whereas it is as high as 12/1,000 births in some parts of Ireland and Wales. In 1982, in China the incidence ranged between 2.7/1,000 and 10.6/1,000 births with a high incidence of 7.25/1,000 reported from rural China which has subsequently reduced. Craniorachischisis and iniencephaly are much more frequently seen in Northern China.

A recent systematic review of birth prevalence of NTDs in India found that the overall birth prevalence of NTDs is 4.1/1,000. Anencephaly is more prevalent at 2.1/1,000 births while spina bifida ranked second at 1.9/1,000 births. The incidence of NTDs in North India reported is 3.9–9/1,000 live births while in certain pockets in South India it is as high as 11.4/1,000 live births. The incidence of NTDs in the rural community in India is 6.57–8.21/1,000 live births. The risk of recurrence in the next pregnancy is 4% which increases to 10% and 25% with subsequent pregnancies.

ETIOLOGY

The exact cause of NTDs is not known but the inheritance is multifactorial. A number of environmental factors have been implicated. Hyperthermia, maternal malnutrition, chemicals, maternal obesity, maternal diabetes [insulin-dependent diabetes mellitus (IDDM)], exposure to radiation, alcohol, drugs such as valproate, carbamazepine, trimethoprim, oral contraceptives and clomiphene during pregnancy and specific nutritional deficiencies in mothers during pregnancies such as folic acid deficiency and its role in homocysteine metabolism, vitamin B_{12} deficiency, zinc deficiency, myoinositol and vitamin A seem to play a role in the etiology of NTDs. Periconceptional supplementation of folic acid to women in the child bearing age group had brought down the risk for NTDs by 70%, thus implying a role of maternal folic acid deficiency in the pathogenesis of NTDs. There appears to be a genetic predisposition and mutations in the folate responsive or folate dependent pathways may play a role. NTDs are also seen in Trisomy 13 and 15.

PATHOGENESIS

Failure of normal induction in the process of neurulation at the 3rd week of gestation is responsible for primary NTDs. The neural plate develops from the ectoderm in the 3rd week of gestation. Epidermis is formed from ectoderm by inhibition of bone morphogenetic protein (BMP) and the Wingless (Wnt) signaling pathway. The proliferation of cells within the neural plate causes invagination forming the neural groove in the midline flanked by ridge like neural folds which takes place by day 20 **(Fig. 1)**. Some cells differentiate and migrate to form the neural crest on the lateral surface of the neural tube. The neural folds bend inwards due to changes in the shapes of neural cells to bring the tips of the folds into apposition. Then there is fusion of the tips of the folds leading to formation of the neural tube. This process is called neurulation. The closure of the neural tube initially occurs in the center followed by rapid closure both rostrally and caudally. The rostral end closes by day 23 and the caudal end by day 27 of gestation. Failure of closure of the neural tube leads to formation of most of the NTDs. The vertebral column develops around the central notochord which develops from the notochordal plate.

PATHOPHYSIOLOGY

Genetic Predisposition
Neural tube defects (NTDs) are inherited by a multifactorial trait that follows a threshold model. Those who exceed a threshold liability due to genetic and environmental factors, develop the trait while those below the threshold do not. In NTDs, genetic factors are implicated by the increased recurrence risk for parents of an affected child as compared to general population and familial aggregation of the various types of NTDs. But the recurrence risk still remains low at 3%, much lower than traits caused by a single fully penetrant mutation. Therefore, these defects arise from an interplay of a number of genes along with gene-environmental interactions. Recent studies have implicated polymorphisms in human Vangl 1 and Vangl 2 in infants with NTDs. However, single nucleotide polymorphisms (SNPs) can occur in unaffected persons also.

Pathway relationships associated with NTDs are being increasingly recognized such as the planar cell polarity (PCP) signaling pathway [Wnt and sonic hedgehog (SHH) pathways], DNA methylation pathways, chromatin remodeling and transcription factors. Evaluation of multiple genes may be required in an individual to determine risk as well as appropriate preventive therapy.

Environmental Triggers
Factors found to have an increased risk in nonsyndromic spina bifida are history of previous affected pregnancy (RR 30-fold), inadequate maternal intake of folic acid (RR 2–8 fold increased risk for

MMC and anencephaly), pregestational diabetes mellitus (RR 2–10 fold) and antiepileptic drugs—valproic acid and carbamazepine (RR 10–20 fold). Hyperglycemia and hyperinsulinemia increase risk for NTDs. Also maternal periconceptional rise in sugar levels that increase the glycemic index even in nondiabetic women have an increased NTD risk. In addition, a number of factors are suspected to play a role as a risk factor such as maternal vitamin B_{12} status (RR three-fold), maternal obesity (RR 1.5–3.5 fold), maternal hyperthermia (RR two-fold), maternal diarrhea (RR 3–4 fold). Some other risk factors studied but not established are gestational diabetes, chlorination of drinking water, electromagnetic fields, pesticides and hazardous wastes.

Role of Folic Acid

The exact mechanism explaining the association between NTDs and folate is still unknown. The success of folic acid supplementation is because folate metabolism contributes to many biological functions. Folate coenzymes take part in many functions such as DNA and purine synthesis and amino acid interconversion. The methionine produced when homocysteine gets converted to methionine, is used for synthesis of S-adenosyl-methionine (SAM), the body's main methyl donor. SAM participates in methylation of DNA and histones modulating gene expression. Mutations occur in one of the genes encoding enzymes in the homocysteine metabolism as in 5, 10 methylenetetrahydrofolate reductase

(MTHFR). There is an association between a MTHFR variant and mothers of infants with NTD which account for 15% of preventable NTDs.

Maternal Autoantibodies

Neural tube defects can occur in babies of women who had maternal antibodies against folate receptors. The hypothesis is that these autoantibodies block the binding of 3H FA to folate receptors on placental membranes possibly leading to reduced CNS folate which may be responsible for NTDs. In future, this may lead to clinical testing in first pregnancies to adjust the dose of folic acid supplementation in subsequent pregnancies.

Teratogen

Teratogens such as retinoic acid (RA) and antiepileptic drugs are particularly important in the etiology of NTDs. Vitamin A is an essential vitamin for many biological functions. Interestingly in animal embryos, RA can induce NTDs but inactivation of RA synthesis genes or receptor genes in mice lead to high rates of NTDs. Similarly, excessive exposure of human embryos to RA is teratogenic and leads to embryopathy but vitamin A deficiency can also increase the risk of NTD. There is an association of increased risk of MMC with in utero exposure to valproic acid or carbamazepine either as monotherapy or along with other antiepileptic drugs (AEDs). The exact mechanism for increased risk is not known but this happens only when there is a genetic predisposition to the teratogenic effects of valproate.

PREDISPOSED HOST FACTORS: MOLECULAR AND EXPERIMENTAL MODELS

Studies on vertebrates have found a number of factors that are essential for formation of neural tube and its proper closure. It has been suggested that some host factors which are derived from mesoderm are essential to induce neurulation. These factors are chordin, noggin and SHH. The neural tube is patterned along three axes namely anteroposterior, dorsal-ventral and right-left axis as a response to the expression of intrinsic patterning genes and embryonic signaling pathways. The three opposing signal pathways are SHH, Wnt and BMP. SHH induces the differentiation of the floor plate. Fibroblast growth factor, NOTCH, and RA signaling also contribute to neural fate determination. Caudal identity and telencephalic patterning depend on the actions of FGF, Wnt and RA pathways. Homeotic Hox and family transcription factors affect segmental identities and hindbrain features.

CLINICAL PHYSIOLOGY

Failure of closure of the neural tube results in communication with the amniotic cavity and release of substances such as alpha fetoprotein (AFP) and acetylcholinesterase into the amniotic fluid. These substances when found in amniotic fluid serve as biochemical markers of a neural tube defect. Maternal serum AFP

(MSAFP) also rises and can be used as a screening test at 16–18 weeks of gestation to identify pregnancies with risk of NTD.

The clinical presentation depends on the stage of the embryological defect in the process of development of neural tube **(Table 1)**.

CRANIAL DYSRAPHISM

Anencephaly is a NTD due to absence of brain calvaria and is incompatible with life. Encephalocele is formed when there is herniation of brain and meninges through defect in calvaria. Craniorachischisis is defined as anencephaly associated with continuous bony defect of spine with exposure of neural tissue. Iniencephaly is a rare NTD characterized by dysraphism of occipital region classically accompanied by retroflexion of neck and trunk.

SPINAL DYSRAPHISM

Spina Bifida Occulta

This is a common NTD affecting at least 5% of the population. The anomaly consists of a midline defect of the vertebral bodies without involvement of spinal cord or meninges seen usually in the lower lumbar region at L5 S1 levels. The patients are asymptomatic with no neurological signs and the anomaly is detected accidentally on radiographic studies. No treatment is required.

In 10% of certain occult spinal dysraphisms, there may be cutaneous markers over the location of the defect such as tuft of hair, midline lipoma or angioma, pit, lump or dermal sinus over the back **(Fig. 2)**. The roentgenogram of the spine reveals a defect in closure of the posterior vertebral arches and laminae. However, sometimes there may be associated developmental malformations of the spinal cord such as syringomyelia, diastematomyelia or a

Figure 2 Midline lumbosacral cutaneous marker: hypertrichosis

Table 1 Pathological characteristics and their clinical correlates in neural tube defects (NTDs)

Embryological defect	Clinical correlate
Defect of neural folding and formation	Meningomyelocele and anencephaly
Disordered postneurulation development	Encephalocele
Incomplete dysjunction	Dermal sinus, dermoid and epidermoid tumors
Premature dysjunction	Spinal cord lipomas
Disorders of gastrulation	Split cord malformation, neurenteric cysts
Disordered secondary neurulation	Thickened filum terminale, myelocystocele
Failure of development of caudal neuraxis	Sacral agenesis

tethered cord. Ultrasonography (USG) may be helpful for diagnosis in the newborn. Keeping the possibility of these associated malformations in mind, every case of occult spinal dysraphism must be investigated with magnetic resonance imaging (MRI).

Dermal Sinus

A small opening on the skin leads into a narrow passage which may be a dead end or pass through the dura and act as midline cutaneous makers over the location of a meningocele or encephalocele and are found in the lumbosacral or occipital region. Recurrent meningitis of unknown origin should alert one to look for a small dermal sinus. Associated conditions such as diastematomyelia and tethered cord should be looked for and require surgical intervention.

Meningocele

When the meninges protrude out or herniate through the bony defect in the posterior vertebral arches or anterior sacrum, it is termed meningocele **(Fig. 3)**. In most cases, the spinal cord is normal but sometimes there can be tethered cord, syringomyelia or diastematomyelia. Clinically, the meningocele presents as a fluid-filled fluctuant midline lesion. Transillumination is positive as there is no nervous tissue present in the lesion.

Meningomyelocele

This is the most severe and most complex form of spinal dysraphism involving skin, vertebral bodies, meninges, nerve roots and spinal cord **(Fig. 4)**. The dysplastic neural tube is a red, flat disorganized fleshy mass of tissue located in the middle of a cerebrospinal fluid (CSF) containing sac. Usually the sac is present but may rupture leading to CSF leak. Sometimes, the placode is covered by epithelium and a sac may be absent. This is termed myeloschisis.

The location of MMC may be variable but is most often found in the lumbosacral region. The nature and severity of the neurological impairment depends on its location and size. Thoracic defects are more complex and have more complications. MMC in the cervical region are more protuberant. Neural tissue does not lie exposed but is usually covered by thick epithelium. The o tcome is therefore better in these lesions. It can be tethered to adjacent dura. X-ray of the MMC shows the defect of the vertebral arch.

The clinical manifestations of MMC are weakness or paralysis of the lower limbs and bladder and bowel sphincter dysfunction and complications like infection. Hydrocephalus is frequently present **(Fig. 5)**. Often the MMC is associated with developmental

Figure 4 Meningomyelocele

dysplasia of the hip (DDH) and congenital talipes equinovarus (CTEV) or club foot. The spectrum of clinical manifestations varies from severe sensory loss and trophic ulcers to only mild sphincter disturbances. Although intelligence is normal in the majority, cognitive and language difficulties may be present. This may further affect the quality of life of these children.

Urinary Tract and Bowel Dysfunction

Bladder dysfunction occurs because of the interruption of nerve roots in the sacral region as well as fiber connections between brainstem and sacral cord. Additionally, overflow incontinence, loss of sacral tone, loss of sacral and rectal sensations and loss of det usor muscle activity occurs. Normal bladder control is seen in only 0% of patients. Fecal incontinence and constipation are two common problems encountered in a child with MMC.

COMPLICATIONS

Progression or worsening of symptoms in terms of weakness, pain, gait, bladder or bowel function can result from tethering of cord or restriction of growth of spinal cord. Tethered cord may be present even when the child is neurologically asymptomatic. Presence of brainstem symptoms may suggest Chiari II malformation or tethered cord. The two main late complications are hydrocephalus and renal failure.
Figure 3 Meningocele

Figure 5 Hydrocephalus and spinal dysraphism in a neonate

Hydrocephalus occurs in 75–80% in children with MMC, while 90% of MMC located in the thoracolumbar region have hydrocephalus. Arnold Chiari II malformation, the most common cause of hydrocephalus in MMC (95%), consists of downward displacement of cerebellar vermis and cerebellar tonsils with the thin long medulla lying parallel to upper segments of atrophic cervical spinal cord. The clinical features are progressive hydrocephalus, secondary brainstem dysfunction, feeding and respiratory complaints including apnea. Hydrocephalus usually develops secondarily after Chiari II malformation because the herniation blocks the hindbrain CSF outflow. In 50–85% of patients, aqueductal stenosis or atresia may also contribute or lead to the hydrocephalus.

Hydronephrosis and renal failure occur following bladder dysfunction and urinary incontinence. Urinary tract infection, particularly bladder infection is seen frequently and vesicoureteral reflux develops by 2–3 years. Renal failure is a late but fatal complication.

Delayed deterioration after repair of MMC may be due to infection, hydrocephalus, malfunctioning or infected shunt, scoliosis, tethered cord, hydromyelia, syringomyelia or a second lesion of occult spinal dysraphism such as dermoid, epidermoid or arachnoid cyst. Additionally, shunt infection is seen in 25%, intellectual deterioration may occur with repeated attacks of meningitis or ventriculitis, epilepsy is present in 10–30%, ocular problems in 30% and all these may contribute to the psychosocial problems in these children.

APPROACH TO DIAGNOSIS

History of any older children born with neural tube defect or associated congenital malformations should be asked for. Maternal illnesses such as diabetes and epilepsy should be noted. Ask for maternal intake of antiepileptic drugs such as valproate, carbamazepine and other teratogens. Symptoms of the child such as movements of the lower limbs, dribbling of urine or bowel incontinence should be noted. Ask for any other obvious congenital anomalies noticed by the parents. In older children, history regarding surgery for lesion or shunt for hydrocephalus should be asked and history about intellectual functioning, gait and psychosocial adjustment should also be taken. Examination is summarized in **Box 1**.

BOX 1 Examination in a child with neural tube defect

- General physical examination for any other congenital anomaly such as club foot, hip subluxation, scoliosis, kyphosis, signs of Chiari II malformation

- Examination of the back to look for the neural tube defect; and presence of associated cutaneous markers

- *Examination of the lesion:* To make a diagnosis of the lesion, presence of leaking, establish the extent and severity

- *Examination of the head:* For head shape and head circumference, anencephaly, encephalocele, hydrocephalus, sutural separation, anterior fontanel, dilated veins on scalp and forehead

- *Neurological examination:* To look for movement of lower limbs, tone, power, reflexes and sensory deficits below the level of the lesion particularly the lower limbs

- *Assessment of bladder function:* Urinary incontinence, urinary retention, spastic bladder, hydronephrosis, urinary tract infection, loss of sphincter tone and loss of sensation over sacral region

- *Examination of anus:* Look for rectal prolapse or patulous anus, sacral or rectal loss of sensation.

INVESTIGATIONS

Antenatal Diagnosis

During pregnancy, MSAFP and fetal ultrasound are the two screening tests that help to identify fetuses at a higher risk for developing MMC or anencephaly. Raised concentration of amniotic AFP in early pregnancy indicates open NTD but there is no such increase in closed NTD. Higher the levels of MSAFP suggest a higher possibility of a NTD. MSAFP screening at 16 weeks of gestation is 64% accurate. AFP levels twice the normal values or more are found in 95% of anencephalic, 80% of open spina bifida and only 2% of normal unaffected pregnancies. Thus implying a high sensitivity, but AFP is not specific for NTD as it can be elevated in open ventral wall defects such as gastroschisis and omphalocele.

Acetylcholinesterase, is another biochemical marker in the amniotic fluid, also produced by fetal CNS, that correlates with MSAFP or amniotic fluid AFP and adds to specificity and sensitivity. A combination of increased ACH and increased AFP is stronger evidence for presence of NTD and has an accuracy of 97%.

Fetal USG helps in differentiating ventral wall defects from NTD and to identify other anomalies, spontaneous leg and foot activity, other spine abnormalities and Chiari II malformation. Confirmation of type and extent of NTD is possible with USG. This serves as a guide for deciding on medical termination of pregnancy (MTP) and therefore preventing births with NTD.

A comparison of accuracy of these screening tests reveals that fetal USG is 60% accurate in low risk pregnancies and 100% accurate when done to confirm a lesion suspected on previous USG. Neither USG alone nor AFP alone is sensitive or specific enough but has a high predictive value when used in combination. Prenatal MRI with ultra fast T2-weighted sequence can visualize the defect and characterize Chiari II and other malformations. 17% of all fetuses with NTD have chromosomal abnormalities such as trisomy 13 and 18, translocation or triploidy. In prenatally detected spina bifida fetal karyotyping and cytogenetic analysis can be done.

Investigations after Birth

X-ray chest and spine, USG of the NTD, head and abdomen, CT scan/MRI brain and spine, karyotyping and cytogenetic analysis should be done. Evaluation and monitoring of genitourinary system by repeated periodic urine culture, renal scans, renal USG, urodynamic studies such as VCUG, cystometrogram (CMG) as required, is a must to reduce need for surgery and to reduce morbidity and mortality.

MANAGEMENT

A multidisciplinary team consisting of the obstetrician, neonatologist, pediatric neurologist, radiologist, pediatric surgeon, neurosurgeon, pediatric nephrologist, neonatal nurse, orthopedic surgeon, physiotherapist and social worker is required for management of a baby born with a NTD.

Parental counseling Antenatal diagnosis or detection at birth of a NTD has to be conveyed to the parents by a knowledgeable and compassionate individual explaining the condition and its extent and severity and also the treatment options available and the prognosis, in a way that parents will understand to help them to accept the condition and take appropriate informed decisions for the child. The parents will require further counseling and support as the child grows.

Fetal repair Prenatal surgery for myelomeningocele by hysterotomy has resulted in correction of hindbrain herniation, reduces the need for shunting and improves motor outcomes at 30 months but may be associated with maternal and fetal risks.

Immediate medical management The neonate should be admitted in the neonatal intensive care unit (NICU) and provided supportive care, with the baby in the prone or lateral position. The lesion must be kept moist by covering with sterile saline dressings. A thorough examination and imaging for ruling out other congenital malformations should be done. Before planning surgery, detailed neuroimaging of spine and head is mandatory.

Surgical Management

Surgery should be performed early to prevent neurological worsening. Surgery consists of repair or closure of the defect. If infection is present, then surgery should be deferred to after treatment with intravenous or intrathecal antibiotics. The timing of surgery depends on whether the lesion is open or closed. If the lesion is open with CSF leak, it should be operated within 24 hours and closed lesions within 48 hours.

Lorber's criteria Surgery is not to be done in the presence of: (1) severe paraplegia at or above L3 level (2) kyphosis or scoliosis (3) gross hydrocephalus (4) associated gross congenital anomalies (5) intracerebral birth injuries or (6) pre-existing ventriculitis. The only treatment option for these children is medical and supportive care.

In addition, other surgical procedures may be needed. (a) Shunt surgery for hydrocephalus (b) Surgical correction of orthopedic conditions (c) Surgical treatment of bladder dysfunction (d) Shunt surgery and sometimes surgical decompression of posterior fossa in Chiari malformation (e) Delayed deterioration after MMC repair may require surgical repair of tethered cord, revised shunting, fenestration of syringomyelia to prevent further deterioration.

PROGNOSIS

Anencephaly is incompatible with life. Untreated MMC has a high mortality rate of 50% with most deaths in the first 4 years of life. If aggressively treated, the mortality rate in MMC is 10–15%. 80–90% of MMC develops hydrocephalus and most require shunt. Intelligence is normal in 70% of cases and almost 60% attend grade appropriate school. Repeated episodes of meningitis or ventriculitis affect cognition. These children are more prone to learning difficulties and seizure disorders. Early detection, correct diagnosis and prompt treatment of NTDs improve the outcome.

Long-term outcome studies have reported that 1-year survival rate is 87% which implies that about 78% all patients with MMC will live to the age of 17 years. There is an increased risk for lower limb weakness or paralysis, tethered cord, syringomyelia, bladder and bowel incontinence and orthopedic problems. Bowel incontinence is seen in 14% and urinary incontinence may be present in 25%. Renal dysfunction is an important cause of death.

PREVENTION

The currently accepted strategies are (a) antenatal screening for NTD with medical termination of affected pregnancy (b) folic acid supplementation and its role in both primary and secondary prevention.

Primary prevention Periconceptional folic acid supplementation **(Box 2)** is a simple and effective strategy that can prevent debilitating malformation and has brought down the incidence by 70%. Food fortification and improving the diet are other accepted methods. Strategies to add vitamin B_{12} and other nutrients such as zinc, vitamin A, myoinositol, etc. are being studied.

BOX 2 Prevention of neural tube defects: periconceptional folic acid supplementation

Indication 1: All prospective mothers
- *Dose:* 0.4 mg/day
- *When:* 2 months prior to conception and 3 months after conception

Indication 2: Prospective mothers with previous child with NTD
- Dose: 4 mg/day
- *When:* 2 months prior to conception and 3 months after conception

Note: For prospective mothers taking AEDs, folic acid–dose and duration as in Indication 2. Effectiveness is controversial.

Secondary prevention Family counseling is extremely vital when there is an affected child because recurrence risk is 4% after one affected child, 10% after two affected children. MTHFR polymorphisms should be studied in multiple recurrences of NTD. Prenatal screening and termination of the affected pregnancy prevents birth of babies with NTDs and periconceptional folic acid in subsequent pregnancies is advised.

IN A NUTSHELL

1. Neural tube defects are one of the most common congenital anomalies of the CNS.
2. Failure of spontaneous closure of the neural tube is responsible for most neural tube defects.
3. The common NTDs are spina bifida occulta, meningocele, MMC, anencephaly and encephalocele.
4. The inheritance is multifactorial as a result of genetic and numerous environmental factors.
5. The clinical presentation consists of the spinal lesion accompanied by weakness or paralysis of lower limbs, bladder and bowel dysfunction and orthopedic problems.
6. Complications of NTDs are meningitis, hydrocephalus due to Chiari II malformation, renal failure and hydronephrosis.
7. Antenatal diagnosis is possible with maternal and amniotic fluid AFP, ACH and fetal imaging.
8. Treatment consists of parental counseling, medical and surgical management such as repair of NTD and shunting.
9. *Prevention:* Periconceptional folic acid has brought down the occurrence by 70%.
10. The extent and involvement of the nervous tissue decides the severity and the outcome.

Chapter 42.5
Brain Malformations
Jatinder S Goraya

Brain malformations (BM) are the structural abnormalities of the brain that result from defects during early stages of embryological development of the brain. Given the complex nature and wide range of functions of the brain, brain malformations can result in myriad symptoms and signs in the affected child. Brain development is under the influence of several genetic factors, and genetic basis of many of the commonly known brain malformations has been elucidated and defective genes identified facilitating the genetic diagnosis and counseling.

EPIDEMIOLOGY

Advent of neuroimaging techniques especially the magnetic resonance imaging (MRI) resulted in the increased recognition of brain malformations. Brain malformations have been estimated to occur with an incidence of approximately 3.32/1,000 and the prevalence of approximately 2.21/1,000. The incidence and prevalence of the individual brain malformation is described under the specific malformations below. Data from developing countries is not available.

CLASSIFICATION

The classification of brain malformations continues to evolve as advances in genetics and neuroimaging add new information. Classification of malformations of brain on embryological and anatomical basis is easy to understand and follow **(Table 1)**. Classification systems based on underlying molecular or genetic defects are too complex and beyond the scope of this chapter.

EMBRYOLOGICAL CONSIDERATIONS

At the end of primary neurulation, the rostral end of the neural tube organizes to form three primary vesicles: (1) the hindbrain (rhombencephalon), (2) the midbrain (mesencephalon) and (3) the forebrain (prosencephalon). Soon three flexures (bends) make their appearance—the mesencephalic flexure at the midbrain level, the cervical flexure at the junction of hindbrain with spinal cord and the pontine flexure in the hindbrain. The forebrain divides and develops into telencephalon, and the diencephalon from

Table 1 Classification of brain malformations

- Disorders of forebrain development

  - Isolated brainstem abnormalities
- Malformations of cortical development
  - Lissencephaly and subcortical band heterotopias
  - Nodular heterotopias
  - Polymicrogyria
  - Schizencephaly
  - Focal cortical dysplasias

which optic vesicles arise bilaterally. The cerebral hemispheres develop from telencephalon, and expand to completely cover the diencephalon. The hindbrain divides into rostral metencephalon from which the pons and the cerebellum develop, and caudal part becomes myelencephalon which eventually become medulla oblongata. The mesencephalon develops into midbrain.

ETIOLOGY

Genetics plays a major role in the causation of various brain malformations. Both autosomal and X-linked forms of brain malformations have been reported. Specific gene defects have been identified and clinically exploited for diagnostic purposes (see individual brain malformations vide infra). Sporadic occurrence as well as chromosomal imbalance may account for some forms of brain malformations. In addition, brain malformations may be associated with certain inborn errors of metabolism such as nonketotic hyperglycinemia (agenesis of corpus callosum), Zellweger syndrome (polymicrogyria), glutaric aciduria type 2 (cerebellar vermis hypoplasia) and disorders of glycosylation (pontocerebellar hypoplasia). Some congenital malformations syndromes such as Smith-Lemli-Opitz syndrome, Miller-Dieker syndrome, Rubinstein-Taybi syndrome, etc. also have associated brain malformations. Exposure to environmental factors such as ionizing radiation, therapeutic drugs, intrauterine infections such as cytomegalovirus are known to cause certain types of brain malformations.

CLINICAL FEATURES

Wide range of clinical manifestations can be seen as a consequence of underlying brain malformation. The age of onset varies from birth (in some cases may be intrauterine) to adulthood depending upon the severity and complexity of the brain malformations. Neonatal seizures including refractory epileptic encephalopathies, hypotonia, feeding or breathing difficulties tend to be the earliest manifestations. During infancy and early childhood, developmental delay, seizures, including infantile spasms, partial seizures and other refractory epilepsy syndromes such as Lennox-Gestaut syndrome may unmask the underlying brain malformations. Intellectual disability, developmental language disorders, specific learning difficulties, behavioral disability, epilepsy, motor difficulties secondary to spasticity, ataxia, weakness or movement disorder become evident as the children grow old. Special sensory deficits such as blindness may be encountered. Although all these function deficits are not specific for brain malformations, certain phenotypical characteristics may point to a specific brain malformation. For example, occurrence of infantile spasms in a female infant with retinal lacunae points to Aicardi syndrome. Zellweger syndrome has characteristic facies which helps in the diagnosis. Brain malformations are also increasingly being diagnosed during routine or dedicated prenatal ultrasonographic examinations. Signs and symptoms that are relatively specific for certain brain malformations are discussed under individual malformations of the brain.

DIFFERENTIAL DIAGNOSIS

As mentioned above, clinical presentation of brain malformations can be simulated by several congenital syndromes without identifiable brain malformations as well as by acquired neurological disorders. The diagnosis of brain malformations should be suspected in any infant with early onset neurological symptoms such as developmental delay, seizures or hypotonia in the absence of known metabolic derangements such as electrolyte

imbalance, hypoglycemia or hypocalcemia and infectious etiology. Though neuroimaging has rendered the diagnosis of common brain malformations rather easy, it requires the expertise of an experienced neuroradiologist to detect subtle alterations in the brain anatomy that is often seen with focal cortical dysplasia (FCD), heterotopias and polymicrogyria. Neuroimaging with magnetic resonance provides anatomical diagnosis of specific malformation in most of the cases with its ability to see brain in various planes, though further evaluation especially genetic may sometimes be required to reach a final diagnosis and for genetic counseling.

TREATMENT

As a rule, brain malformations do not have any specific treatment. Treatment is largely symptomatic and multidisciplinary. Antiepileptic medications are used for control of seizures. Seizures tend to be refractory frequently and polypharmacy is not uncommon. Drugs are also sometimes needed to treat spasticity, sialorrhea and movement disorders. Physical, occupational and speech therapy are generally required as patients frequently manifest cerebral palsy, speech and swallowing difficulties. Orthopedic, neurosurgical, ophthalmological consultations are needed in appropriate cases. Genetic diagnosis and counseling is important where such facilities are available. Risk of recurrence and possibility of prenatal diagnosis should be communicated to prevent the birth of another affected child after the diagnosis of brain malformation in an index case.

The outcome in brain malformations depends upon the underlying malformation. Severe and diffuse malformations tend to have grave prognosis for development, seizure control, and survival.

SPECIFIC BRAIN MALFORMATIONS

Holoprosencephaly

This brain malformation results from failure of the forebrain or prosencephalon to divide in the midline into two distinct cerebral hemispheres. Midline facial defects are frequently seen. This is the most common developmental anomaly of the forebrain. It occurs in 1 in 250 pregnancies but only in 1 in 10,000 live births as majority of the affected fetuses do not survive till delivery.

Holoprosencephaly (HPE) is classified according to the degree of separation of the cerebral hemispheres: Alobar, semilobar, lobar and a midline interhemispheric variant. In addition to nonseparation of the cerebral hemispheres, there is variable degree of nonseparation of hypothalamic, thalamic, lentiform and caudate nuclei. The alobar holoprosencephaly is the most severe, showing almost complete absence of separation of the cerebral hemispheres with characteristic midline single ventricle (a crescent-shaped monoventricle) which may communicate with a dorsal cyst. The corpus callosum, falx cerebri and interhemispheric fissure are absent as are the olfactory bulbs and tracts. Third ventricle is absent owing to nonseparation of thalami and hypothalami. In the semilobar HPE, an intermediate form of HPE, separation of the cerebral hemispheres is restricted to the posterior part and is absent anteriorly. As an accompaniment, corpus callosum shows absence of genu and body and only splenium is present posteriorly. The frontal horns of lateral ventricle are absent and only occipital horns and trigones are present. Septum pellucidum is absent and third ventricle tends to be small due to partial separation of deep gray nuclei. Lobar HPE is the mildest form, and here the lack of separation is restricted to the most rostral and ventral parts of the cerebral hemispheres. Rudimentary frontal horns may be present and only genu of corpus callosum is absent. In the midline interhemispheric variant (syntelencephaly), cerebral hemispheres show lack of separation across the midline affecting the posterior frontal and parietal lobes with absent corpus callosum in the corresponding region. Anterior frontal lobes, basal forebrain and occipital lobes are normally separated. HPE severity varies across a spectrum and classification of an affected patient into a specific subtype may not be possible. With the advent of advanced neuroimaging techniques, milder forms are being increasingly recognized.

Both environmental and genetic factors may be associated with the causation of HPE. Maternal diabetes, fetal exposure to alcohol and retinoic acid have the strongest association. Other reported risk factors such as hypocholesteremia, viruses, toxins and medications have also been reported. HPE can also be seen with chromosomal abnormalities such as trisomy 13 or 18, congenital malformation syndromes such as Smith-Lemli-Opitz syndrome, Rubinstein-Taybi syndrome and Pallister-Hall syndrome. HPE occurring as a single gene disorder in the form of autosomal dominant and autosomal recessive forms has been described. Several genes namely sonic hedgehog (SHH**)**, *ZIC2* (ZIC family member 2 or *zinc finger protein of the cerebellum* 2), *SIX3* (SIX homeobox 3) and transforming growth factor beta (TGFB induced factor (TGIF) have been associated with the occurrence of HPE.

Clinically, midline facial anomalies frequently accompany HPE. Facial midline abnormalities include hypotelorism, flattened nasal bridge, median cleft lip and palate, or a single median maxillary central incisor. Cyclopia, with the presence of a single median eye and a proboscis, can be present. Presence of normal facies is, however, not unusual. Other children with HPE come to attention through the occurrence of variable degree of developmental delay, tone abnormalities, and epilepsy with partial or generalized seizures. Feeding and swallowing difficulties are also very common. Patients tend to have microcephaly in the absence of hydrocephalus which may complicate the clinical course in some children. Endocrinopathies are common due to hypothalamic involvement and especially frequent is the diabetes insipidus. Growth hormone deficiency, hypocortisolism, and hypoparathyroidism may be seen less commonly. Generally, severity of clinical manifestations is commensurate with the severity of HPE. Diagnosis is by MRI.

No specific treatment is available and management is largely symptomatic. Epilepsy, spasticity and dystonia require appropriate medication. Special attention need to be paid to the feeding and swallowing dysfunction to prevent malnutrition and may require gastrostomy tube. Diabetes insipidus and other endocrinopathies need early detection and intervention. Surgical treatment for hydrocephalus or spasticity may be needed. The morbidity and mortality in HPE varies with the severity of the disease. Longer survival is common with milder form. Causes of death include aspiration pneumonia, severe dehydration from diabetes insipidus and rarely intractable epilepsy.

Prenatal diagnosis can be achieved through a combination of prenatal ultrasonography, fetal MRI and gene testing. The risk of recurrence is about 6% in isolated HPE. In familial cases where causative gene has been identified, prenatal diagnosis is through genetic testing by means of amniocentesis or chorionic villous biopsy.

Agenesis of Corpus Callosum

Corpus callosum is the largest white matter tract in the brain connecting the two cerebral hemispheres and providing the pathway for communication between them. It develops between the 8th week and 14th week of fetal life and the axons that traverse it connect the homotopic regions of the cerebral hemispheres. Agenesis of the corpus callosum (ACC) is the most common brain malformation found in 1 in 3,000 livebirths.

Agenesis of corpus callosum can be partial or complete. It can occur as an isolated entity or more commonly associated with other malformations of brain or cortical development. Some patients have abnormalities in organ systems outside central nervous system commonly affecting renal, musculoskeletal or ophthalmological structures and defining specific genetic/malformation syndromes.

Genetic factors play major role in the causation of ACC. Increased maternal or paternal age is associated with higher risk of occurrence of ACC. Chromosomal aberrations have been identified in a significant number of patients with ACC. There is large list of single gene disorders as well as congenital malformation syndromes associated with ACC. Certain inborn errors of metabolism such as pyruvate dehydrogenase deficiency, nonketotic hyperglycinemia and pyruvate decarboxylase deficiency have ACC as a part of the clinical spectrum. Of the environmental factors, alcohol consumption by mothers during pregnancy is associated with occurrence of ACC (fetal alcohol syndrome).

Clinically, a wide range of clinical manifestations can be seen with ACC and the onset of symptoms can be during infancy to late childhood. ACC can rarely be asymptomatic. Commonly ACC is associated with developmental delays, mental retardation, epilepsy or cerebral palsy. Deficits in cognitive, social and behavior domains, autism and attention deficit hyperactivity disorder (ADHD) has increased prevalence in children with ACC. Children with additional brain malformations (neuronal heterotopias, PMG, etc.) tend to have more severe neurological dysfunction. Some manifestations related to extraneurological involvement may be seen. Children with ACC as part of congenital malformation syndromes have specific dysmorphism suggesting the syndromal diagnosis. The diagnosis of ACC is made by MRI **(Fig. 1)**. ACC may also be detected inutero during the ultrasonographic examination.

Treatment is symptomatic.

Septo-optic Dysplasia

This is a rare brain developmental defect comprising optic nerve hypoplasia, pituitary abnormalities and absent septum pellucidum. Etiologically young maternal age is a risk factor. Fetal exposure to alcohol, smoking, cocaine and certain other toxins or drugs may be associated with increased risk of occurrence of septo-optic dysplasia (SOD). Two genes namely *HESX1* (homeobox, ES cell expressed 1) and *SOX2* (sex determining region Y—BOX 2) have been found in association with SOD.

Figure 1 T1-weighted saggital magnetic resonance (MR) image showing complete absence of corpus callosum. The sulci and gyri on the medial surface appear radiating from the third ventricle

Clinically, the children may come to attention at birth manifesting hypoglycemia secondary to pituitary insufficiency, and are found to have microphallus, undescended testes, and midline birth defects such as cleft lip or palate. Ophthalmological and neuroradiological examination with MRI reveals characteristic findings. Patients with SOD are also prone to other pituitary hormone deficiencies such as adrenocortical hormone, growth hormone, gonadotropic hormone and thyroid stimulating hormone. Many patients have addition brain malformations which may account for occurrence of seizures, developmental delay or cerebral palsy in the affected children.

Treatment of neurological manifestation of SOD is largely symptomatic. Particular attention needs to be given to endocrinological evaluation, treatment and monitoring. Ophthalmological examination and follow-up is necessary.

Disorders of Brainstem and Cerebellar Development

These disorders will be considered together because of co-occurrence of abnormalities of brainstem in patients with cerebellar developmental defects and vice-versa.

Chiari 1 malformation This anomaly refers to the downward displacement of cerebral tonsils of at least 3–5 mm through foramen magnum into the spinal canal. The reasons for downward herniations are not clear through several theories such as traction by tethered cord, and small posterior fossa has been proposed. No clear etiological factor can be identified in majority of the patients.

Clinically, patients may be entirely asymptomatic coming to attention through neuroimaging done for some other purposes. Those who are symptomatic frequently manifest posterior headache that is increased with Valsalva maneuvers. The pain may radiate anteriorly to vertex or downward to neck and shoulders. Compression of brainstem and spinal cord may occur manifesting with long tract signs such as spasticity, hyper-reflexia, urinary incontinence, ataxia or sensory changes. Presentation may be complicated by the development of syringomyelia in some patients.

Treatment where indicated is surgical decompression of the posterior fossa and duraplasty. Milder cases without syringomyelia and those who have displacement of tonsils less than 3 mm may be observed conservatively as spontaneous improvements are known.

Dandy-Walker malformation (DWM) Disturbed anatomy of DWM includes hypoplasia and upward rotation of the cerebellar vermis, cystic dilatation of the fourth ventricle, and an enlarged posterior fossa with upward displacement of the lateral sinuses, tentorium and torcular herophili.

Dandy-Walker malformation can be caused by chromosomal aberrations, often forming the part of presentation of the congenital malformation syndromes such as Axenfeld-Rieger syndrome. Deletions of *ZIC1* (ZIC family member 1 or *zinc finger protein of the cerebellum 1*), *ZIC4* (ZIC family member 4 or *zinc finger protein of the cerebellum 4*), and *FOXC1* (forkhead box C1) genes can also result in DWM.

Clinically the affected persons may be asymptomatic especially when DWM is unassociated with other malformations of the brain. Others present with variable cognitive, language or motors delays. Hydrocephalus can occur as a complication requiring place-ment of a ventriculoperitoneal shunt. Extracranial organ system involvement affecting heart, urogenital tract, gut and limbs occur frequently in patients affected by DWM.

Treatment is largely symptomatic. Hydrocephalus requires shunt placement.

Joubert syndrome (JS) Joubert syndrome and related disorders are the most common inherited congenital malformation of the

cerebellum. The cerebellar malformation includes cerebellar vermis hypoplasia, thick and maloriented superior cerebellar peduncles, and abnormally deep interpeduncular fossa which together produce a characteristic molar tooth sign on brain imaging. These conditions have been described in the chapter on Ataxia.

Malformations of Cortical Development

Development of human cerebral cortex occurs between the 8th week and 24th week of gestation and can be divided into three steps—(1) the neural stem cell proliferation and differentiation, (2) neural migration and (3) cortical organization. Neural stem cell proliferation and differentiation (neurogenesis) begins in the ventricular zone giving rise to cells that will eventually migrate outward to become cortical neurons. The neural migration is guided by the network of axons of radial glial cells under the influence of protein molecules regulated by several genes. The cortical organization involves formation of six-layers of cortical ribbon, formation of sulci and gyri, axon myelination, and synaptic proliferation and pruning. Disruption of any of these processes can result into malformations of cortical development (MCD).

Lissencephaly (LIS)

Lissencephaly, or *smooth brain*, is the result of disruption of the neural migration leading to the formation of abnormally thick cortex and an abnormal gyral pattern in the form of absence of gyral formation (agyria) or the presence of abnormally wide gyri (pachygyria). The thick cortex in LIS is abnormal and consists of four abnormal layers including the deep zone of diffuse neuronal heterotopias. The underlying ventricles are enlarged and dysplastic. Subcortical band heterotopias (SBH) is a related disorder, in which symmetric and circumferential bands of gray matter are located in the subcortical white matter just underneath the cortex and separated from it by a thin band of white matter. The overlying cortex may be normal or mildly immature. The term, *double cortex* has been used to describe the malformation.

Several types of LIS have been described. In most common or classic form, the cortex is four-layered and 12–20 mm thick. The malformation may be diffuse or more severe in anterior (*Lissencephaly 1* or *LIS1* gene) or posterior (Doublecortin or *DCX* gene) head regions. Miller-Dieker syndrome is a form of classical LIS caused by deletion of 17p13.3 and affected children have characteristic facies. The LIS in this disorder has no anterior or posterior dominance. Rare three-layered (X-linked lissencephaly with abnormal genitalia caused by mutations in Aristaless related homeobox gene or *ARX* gene), and two-layered (complete agyria with severe brainstem and cerebellar hypoplasia) forms of LIS have been described.

Clinically children with most common type of LIS are asymptomatic during newborn period. Neurological dysfunction becomes obvious during infancy with developmental delay, poor feeding or tone abnormalities. More commonly seizures bring the affected infants to medical attention. Infantile spasms are the most common type of epilepsy and may later evolve into Lennox-Gestaut syndrome and other forms of seizure may occur. Epilepsy is usually refractory. In some rare forms of LIS, other manifestations such as abnormal genitalia, dysmorphism, etc. may be obvious on clinical examination.

Diagnosis is made by neuroimaging **(Fig. 2)**. Magnetic resonance where available is the modality of choice to diagnose and classify the lissencephaly as well as to detect additional associated brain malformations. Neuroimaging allows the differentiation of various types of LIS as well as the pattern and the severity of the malformations. This coupled with specific clinical characteristics such as dysmorphism, severe microcephaly, abnormal genitalia allows for syndrome diagnosis and helps in directing the appropriate genetic evaluation. Several genes *ARX,*
Figure 2 CT head of a child with lissencephaly showing smooth and thickened cortex. Underlying white matter is abnormally hypodense and ventricles dilatation is apparent
Source: Dr Chandan Kakkar.

DCX, LIS1, RELN (reelin), and *TUBA1A* (Tubulin, alpha 1a) have been recognized to be associated with various types of LIS and are available for clinical testing.

Treatment is generally symptomatic. Since epilepsy is the dominant feature, antiepileptic medications tailored to the specific seizures and epilepsy type are required for effective seizure control.

Cobblestone Malformation

Previously called Lissencephaly type 2, cobblestone malformation or lissencephaly is a severe brain malformation associated with abnormal migration from the brain into the leptomeninges, and frequently with eye anomalies and congenital muscular dystrophy. Cobblestone malformation is characteristically associated with Fukuyama congenital muscular dystrophy (FCMD), muscle-eye-brain disease (MEB) and Walker-Warburg syndrome (WWS).

The brain malformation consists of poor gyral development, cerebral and cerebellar cortical dysplasia, hydrocephalus, brainstem hypoplasia with dysplasia of the inferior olives and dentate nuclei, and hypoplasia of the corticospinal tracts in brainstem and spinal cord. The malformation is the result of defective glycosylation of α-dystroglycan.

These children present with developmental delay, hypotonia, weakness and poor vision. Children with WWS have the severest phenotype followed by MEB and FCMD. These syndromes are inherited in autosomal recessive pattern. Genetic diagnoses through testing for *POMT1* (Protein-O-Mannosyltransferase 1), *POMT2* (Protein-O-Mannosyltransferase 2), *POMGnT1* (Protein O-Linked Mannose N-Acetylglucosaminyltransferase 1), *FKRP* (fukutin-related protein), *FKTN* (fukutin) and *LARGE* (like-glycosyltransferase) is possible and may be needed for genetic counseling and prenatal diagnosis.

Neuronal Heterotopia (NH)

Neuronal heterotopia is diagnosed when masses of gray matter are identified at an abnormal location in the brain and results from arrested neural migration. Two common types include periventricular nodular heterotopia (PNH) and subcortical nodular heterotopias.

In PNH nodular masses of neurons are seen to line the ventricular surface and protrude into the ventricular lumen giving it an uneven appearance **(Fig. 3)**. There may be a single or multiple nodules occurring in symmetric or asymmetric pattern.
Figure 3 MRI brain of a child with nodular heterotopia. There is large nodular mass of gray matter in the white matter of posterior quadrant of right cerebral hemisphere (arrows). The lesion is extending into the lumen of right occipital horn of lateral ventricle
Source: Dr Chandan Kakkar.

Figure 4 MRI brain showing polymicrogyria (multiple small and shallow gyri) in the right fronto-parietal cortex. There is dilatation of the overlying subarachnoid space
Source: Dr Chandan Kakkar.

They may occur as an isolated entity or be associated with other brain malformations. Subcortical nodular heterotopias occur in subcortical location as a large mass of heterotopic neurons expanding the affected cerebral hemisphere.

Epilepsy, usually partial is the most common feature of NH. The onset is variable but may not to occur during infancy or childhood. Mild cognitive deficits and learning difficulties may be encountered. Clinical picture, however, may be altered by associated brain malformations resulting in severe phenotype with microcephaly, mental retardation or refractory epilepsy.

Diagnosis is made on neuroimaging. *FLNA* (*filamin A alpha*) gene mutations may be identified in some families with classic X-linked PNH.

Polymicrogyria

Polymicrogyria is characterized by the presence of multiple small shallow gyri which may or may not be visible macroscopically. It can occur unilaterally; when bilateral can be symmetric or asymmetric. The perisylvian cortex is most commonly involved brain region. PMG mostly occurs as an isolated abnormality but can be associated with other abnormalities of brain development. Intrauterine vascular insult, fetal infections with cytomegalovirus, metabolic diseases such as peroxisomal and mitochondrial disorders, chromosomal abnormalities and multiple congenital anomaly syndromes may be associated with PMG.

Clinically, variable phenotype may occur in PMG. In bilateral perisylvian PMG, patients typically present with oro-lingual-facial dysfunction and epilepsy which together constitute what is called, *"congenital bilateral perisylvian syndrome"*. The oro-lingual-facial dysfunction is caused by the motor dysregulation affecting tongue, oral and facial musculature and results in difficulties with speech, sucking and swallowing, drooling and facial diplegia (pseuobulbar palsy). Epilepsy is common and multiple types of seizures—partial, atonic, tonic, generalized tonic clonic and atypical absences can occur and may become refractory. Continuous spike and wave discharges during slow sleep are frequently associated with PMG.

Brain imaging with MR (1.5T or more) is necessary to diagnose PMG and differentiate from other MCDs with which it may be easily confused **(Fig. 4)**. Cortex in PMG is usually mildly thickened with an irregular gray-white matter junction.

Treatment of PMG is symptomatic.
Schizencephaly (SCH)

Schizencephaly or *cleft brain* is now considered as a subtype of PMG. The cleft is full-thickness extending from the ventricular surface to the subarachnoid space and is lined by PMG. The cleft can be unilateral or bilateral, *open-lip* or *closed-lip*. In open-lip SCH, the walls of cleft do not appose. In closed-lip SCH, the walls of the cleft are apposed and may be fused together; a line of continuity between the lateral ventricle and subarachnoid space may, however, be visible. PMG most often occurs as an isolated abnormality but rarely may be associated with brain malformations.

Clinically, children with SCH present with hemiparesis, motor delays and seizures. Cognitive dysfunction occurs frequently.

Schizencephaly is readily diagnosed on brain MRI. Additional abnormalities, particularly the absence of septum pellucidum and hypoplastic optic nerves are detected in significant number of patients with SCH.

Focal Cortical Dysplasia

The term focal cortical dysplasia is used to describe a wide spectrum of cortical malformations associated with microscopic neuronal heterotopia, dyslamination, and abnormal cell types, namely, balloon cells and dysmorphic giant or cytomegalic neurons. It is the latter neurons that contribute to epileptogenesis. The extent of FCD is variable ranging from focal tranmantle, sublobar, lobar, posterior quadrantic, lobar and hemispheric. FCD are classified based on neuropathological criteria, detailed discussion of which is beyond the scope of this chapter (see MORE ON THIS TOPIC).

Magnetic resonance imaging is the modality of choice for diagnosis. Gross FCDs are easily detected as areas of cortical thickening, abnormal gyration, blurring of the gray-white junction, high signal at the base of the lesion and in the underlying white matter on T2 and fluid-attenuated inversion recovery (FLAIR) sequences. Some FCDs are so subtle that they may be missed even on high-quality imaging.

Most common clinical manifestation of FCD is epilepsy which can arise at any age from newborn period to adulthood. Intrauterine seizures may occur. Extensive FCDs may be associated with developmental, cognitive and motor deficits. Simple or complex partial seizures with or without secondary generalization,

and infantile spasms can occur depending upon the location of FCD and age of the child. Infantile spasms and refractory seizures may have deleterious effects on the neurodevelopment in a young child in the presence of even a small FCD. Some children with FCD have underlying tuberous sclerosis.

Treatment of FCD is centered on anti-epileptic medications due to the fact that seizures are the most common clinical manifestation. In children with refractory epilepsy, respective surgery may be curative but involves extensive presurgical evaluation by experts in epilepsy.

IN A NUTSHELL

1. Brain malformations are an important cause of neurological dysfunction in children.
2. Both genetic and environmental factors are important in the causation of brain malformations.
3. Brain malformations are frequently associated with developmental delay/intellectual disability, epilepsy, behavioral problems and motor difficulties.
4. Brain malformations are readily diagnosed with neuroimaging with MRI.
5. Genetic diagnosis through identification of affected genes is possible and should be done where available.
6. Affected family should be offered genetic counseling and prenatal diagnosis.

Chapter 42.6
Neurocutaneous Disorders
Maya Thomas, Renu George, Karthik Muthusamy

Neurocutaneous disorders, (also referred to as Phakomatoses earlier, origin from the Greek word phakos, meaning *mother spot* or birthmark) include a diverse group of disorders with predominant involvement of the skin and central nervous system tissues, owing to their common origin from the ectoderm. They are now believed to be disorders of neural crest tissue and are also called neurocristopathies. The disorders that are categorized under neurocristopathies include tuberous sclerosis complex (TSC), neurofibromatosis type 1 (NF1), neurofibromatosis type 2 (NF2), epidermal nevus syndrome, neurocutaneous melanocytosis, incontinentia pigmenti and hypomelanosis of Ito. Additional disorders that are considered under phakomatosis are SWS, von Hippel-Lindau syndrome, ataxia telangiectasia, to mention a few. It is important to recognize and be familiar with these skin lesions as they provide a clue to the underlying neurological disorder. Four major disorders will be discussed and the salient features of the rest will be represented in a tabular form.

TUBEROUS SCLEROSIS COMPLEX

Tuberous sclerosis complex is a disorder that can affect multiple organ systems of varying severity and hence has differing clinical expression. It is also called Bourneville disease, after Desire-Magloire Bourneville who is credited with the first detailed description of the cerebral lesions. Birth incidence is estimated to be 1 in 5,800 livebirths.

Etiology
It is an autosomal dominant disorder with complete penetrance but variable expressivity. Only one-third of cases are inherited, the rest are sporadic and occur due to spontaneous mutation. Current molecular diagnostic methods detect mutation in either the TSC1 or TSC2 gene in 85% of TSC patients, both inherited and sporadic. Mutations in TSC2 are five times more common in sporadic cases whereas in the inherited cases, the proportion of mutations in TSC1 and TSC2 are equal.

Pathogenesis
TSC1 gene on chromosome 9q34 encodes hamartin and TSC2 gene on chromosome 16p13.3 encodes tuberin. Hamartin and tuberin complex normally work together and through a cascade of downstream reactions stimulate protein translation, cell growth, and proliferation. The complex inhibit the GTPase Ras homolog enriched in brain (RHEB) which in turn is responsible for activating an important intracellular regulator of cell growth and metabolism known as mammalian target of rapamycin complex 1(mTORC1). Thus, mutations of hamartin or tuberin in TSC lead to hyperactivation of the downstream mTOR pathway resulting in unchecked cell growth and proliferation. This has led to the use of mTORC1 inhibitors like sirolimus and everolimus for the treatment of several clinical manifestations of TSC like cerebral subependymal giant cell astrocytoma (SEGA) and renal angiomyolipomas. Rapamycin, which is also a drug used in TSC makes the dysregulated mTOR pathway return to normal in cells that lack TSC1 or TSC2.

The brain lesions found in TSC, include cortical tubers, subependymal nodules, and SEGA. Heterotopic neurons are commonly scattered in the deep white matter. Cortical tubers are characterized by proliferation of glial and neuronal cells, and loss of the six-layered structure of the cortex.

Clinical Features
The clinical features of TSC depend on the location of the tubers which are predominantly located in the brain, skin, eyes, heart, kidneys and lungs.

Neurological Manifestations
Seizures are the most common presenting symptom in TSC, manifesting in up to 85% of patients. Seizures usually have their onset in the first year of life and type of seizures include infantile spasms or focal seizures like unilateral tonic or clonic seizures, tonic eye deviation or head turning. Seizures may increase in frequency and severity with poor response to antiepileptic medications. Prompt seizure control is important and can prevent development of an epileptic encephalopathy and improve cognitive outcome. Unfavorable prognostic factors include onset of seizures in infancy, multiple seizures types, multifocal spikes on EEG and occurrence of new electroencephalographic (EEG) foci during evolution. Cortical tubers act as epileptic foci and epileptogenesis within these dysplastic neurons is caused by diminished neuronal inhibition, secondary to molecular changes of γ-aminobutyric acid (GABA) receptors, and enhanced excitation, which is secondary to molecular changes of glutamate receptors. Vigabatrin, an inhibitor of GABA transaminase, through this mechanism can control spasms in up to 95% of children.

Tuberous sclerosis complex-associated neuropsychiatric disorders (TAND) is associated with cognitive and behavioral manifestations like profound cognitive impairment in about 30% of individuals. This includes attention-deficit/hyperactivity disorder (ADHD) and autistic spectrum disorder. More than 50% have average intelligence but could have specific impairments in memory, attention or executive skills. The risk for developing autism includes early onset infantile spasms with EEG changes, tubers in the temporal lobe and a mutation in the TSC2 gene.

In about 10% of cases the subependymal nodules transform slowly into SEGAs which are of mixed glia-neuronal lineage. Growth of these lesions at the foramen of Monro can block circulation of the cerebrospinal fluid (CSF), leading to progressive lateral ventricular dilatation and increased intracranial pressure.

Cutaneous Manifestations
Cutaneous lesions are seen in up to 96% of patients with TSC, the most common being facial angiofibroma, also called as adenoma sebaceum. These are pink or red papules that appear between 1 year and 4 years of age in a butterfly distribution over the nose and cheeks **(Fig. 1)**. The lesions increase in number and size through adolescence. Other lesions include hypomelanotic macules known as ash leaf macules **(Fig. 2)**, gingival fibromas, Shagreen patch which are thickened, firm areas of subcutaneous tissue often at the lower back **(Fig. 3)**, and fibrous plaques on forehead and face **(Fig. 4)**.

Other Manifestations
Renal manifestations of TSC are the third most common clinical feature. The lesions seen are angiomyolipomas, isolated renal cyst, autosomal dominant polycystic kidney disease (PKD), and renal cell carcinoma. Angiomyolipomas observed in as many as 80% of individuals with TSC, may be detected in childhood after the third year of age, or in adults. They are usually picked up incidentally but can also cause nonspecific flank pain. The angiolipomas potentially carry a risk of life-threatening hemorrhage from rupture of the dysplastic feeding blood vessel.

Figure 1 Adenoma sebaceum, papular lesions in a butterfly distribution over the nose and cheeks
Figure 2 Hypomelanotic macule or ash leaf macule (arrow) over the leg seen in an infant who presented with infantile spasms

Figure 3 Shagreen patch (arrow) seen over low back are firm areas of subcutaneous tissue

Figure 4 Fibrous plaque on face

Cardiac involvement is usually in the form of rhabdomyomas, seen in 50–60% of patients with TSC. They are benign tumors which develop during intrauterine life and usually undergo spontaneous regression in the first few years of life. They produce symptoms predominantly through outflow tract obstruction, interference with valvular function or they can disrupt electrical conductivity and cause arrhythmias.

Ophthalmic manifestation is mainly in the form of retinal hamartomas present in about 50% of patients and can be found at any age. They appear as rounded, nodular, or lobulated areas on fundoscopic examination and cause no symptoms. Rarely, they affect visual acuity when it impinges on the fovea or optic nerve.

Pulmonary involvement occurs in three forms mainly in adult women and are symptomatic only in 1% of them. These are seen as multifocal micronodular pneumocytes hyperplasia, pulmonary cysts, and lymphangioleiomyomatosis (LAM).

Approach to Diagnosis

Cutaneous lesions of TSC are unmistakable and provide the single main clue to diagnosis. The diagnostic criteria are given in **Box 1**. Diagnosis is made when two major features, or one major and two minor ones are present. Genetic testing and counseling should be offered to individuals with TSC when they reach reproductive age and to first-degree relatives of affected individuals.

Management

Current management guidelines are based on the recommendations of the 2012 International Tuberous Sclerosis Complex Consensus Conference. Once a child is diagnosed with TSC, a complete baseline investigative work-up should be carried out to determine the extent of involvement of each of the organ system. This includes neuroimaging **(Fig. 5)**, ophthalmologic examination, echocardiogram and renal ultrasound. Electroencephalogram needs to be done in case of suspected seizures and when seizure occurrence is unclear such as in unexplained sleep disturbances; behavioral changes or when other alterations in cognitive or neurological function is present. Chest computed tomography is required in women during adulthood.

Epilepsy in TSC is treated with antiepileptic medication depending on the seizure type. Vigabatrin is especially effective in treating infantile spasms in TSC. Adrenocorticotropic hormone (ACTH) can be used if treatment with vigabatrin is unsuccessful. TAND requires comprehensive neuropsychological evaluation and appropriate treatment.

Cortical tubers and subependymal nodules require no treatment. SEGA, if asymptomatic may be left alone but require periodic neuroimaging to ensure there is no growth. Patients with large or growing SEGA, or with SEGA causing ventricular enlargement should undergo surgical resection and cerebrospinal fluid diversion.

Medical treatment with mTORC inhibitors may be used for growing but otherwise asymptomatic SEGA. If skin lesions are rapidly changing or disfiguring, they may be considered for excision, laser or topical application of mTOR inhibitors. Retinal lesions are left alone and re-evaluation is required only if any symptoms arise.

Embolization followed by corticosteroids is first-line therapy for angiomyolipoma presenting with acute hemorrhage. Nephrectomy is to be avoided. For asymptomatic, growing angiomyolipoma measuring larger than 3 cm in diameter, treatment with an mTOR inhibitor is the recommended first-line therapy.

Women who develop LAM with moderate to severe lung disease will require mTOR inhibitors. They may even be candidates for lung transplantation.

NEUROFIBROMATOSIS TYPE 1

Neurofibromatosis type 1 was also known as von Recklinghausen's disease until the end of the 20th century after von Recklinghausen, who in the latter part of the 19th century described tumors arising from the endoneurium of peripheral nerves as *neurofibromas* in two patients. Currently neurofibromatosis includes at least three distinct disorders, referred to as NF1, NF2, and schwannomatosis. NF1 is the most common of the neurofibromatoses, affecting approximately 1 in 3,000 individuals worldwide.

Etiology

Neurofibromatosis type 1 is inherited as an autosomal dominant disorder that affects males and females and all ethnic groups equally. It occurs due to a mutation in NF1 gene localized to chromosome 17q11.2 and spans over 350 kb of genomic DNA.

Pathogenesis

The NF1 gene encodes for the NF1 protein called neurofibromin, which functions as a negative regulator of *Ras*. Loss of neurofibromin results in high levels of activated *Ras*. In many cell types, activated *Ras* is a potent driver of cell proliferation and may be sufficient for tumor formation. In glial cells through downstream intermediates *Ras* regulates cell growth through the Akt/mTOR pathway. Neurofibromin is also a positive regulator of intracellular cyclic adenosine monophosphate (cAMP) levels. Initial studies in Drosophila revealed that learning and memory defects in NF1 mutant flies reflect reduced cAMP generation. Understanding of these pathways has led to clinical trials for new therapeutic drugs.

Clinical Features

Neurofibromatosis type 1 principally affects the skin, bone and peripheral nervous system and is characterized by multiple café-au-lait spots (CLSs), although CLSs are not specific to NF1 alone.
Figure 5   Plain CT brain showing calcified subependymal calcifications (arrow) and MRI brain T2 FLAIR axial image showing subependymal nodules (yellow arrow) seen as projections into the lateral ventricles and high signal intensities involving the cortex which represent cortical tubers (red arrow)

Café-au-lait macules are flat, pigmented spots that are usually visible in room light regardless of background skin pigmentation **(Fig. 6)**. Skinfold freckling **(Fig. 7)** is observed in 85% of NF1 individuals after age 3 years, and is noticeable in the axillae, groins, at the base of the neck, on the upper eyelids, and under the breasts. Neurofibromas **(Fig. 8)** are benign tumors that arise from Schwann cells and may occur anywhere in the body and involve a discrete region of an individual nerve. If it involves multiple nerve fascicles and extends over a length of a nerve and its branches, it is called plexiform neurofibroma. Neurofibromas increase in number after puberty.

Iris Lisch nodules are melanocytic hamartomas which are highly specific to NF1. They appear as dome-shaped pigmented hamartomas on the iris in late childhood, remain asymptomatic and require a slit-lamp examination to be visualized.

Optic glioma **(Figs 9A to C)** occurs in approximately 15% of individuals with NF1, usually beginning in the early years of life. The tumors seen in TSC are pilocytic astrocytomas that may involve the optic nerve, chiasm, and/or hypothalamus. Most are asymptomatic, but some may interfere with vision or cause hypothalamic disturbance such as precocious puberty, or other neurological symptoms.

Figure 6 Café-au-lait macule, hallmark of neurofibromatosis is a flat, hyperpigmented spot

Figure 7 Axillary freckling (Crowe sign), are clusters of concentrated melanin appearing as flat light brown macules

Figure 8 Cutaneous neurofibromas, are fleshy sessile skin lesions that arise from nerves in the skin

Skeletal dysplasia associated with NF1 includes long bone dysplasia and dysplasia of the sphenoid wing. Long bone dysplasia involving tibia is usually visible in early childhood as bowing of the leg. It may also involve other long bones like the fibula, radius, and ulna.

The final diagnostic criterion is the occurrence of a first-degree relative with NF1. Being an autosomal dominant disorder with complete penetrance and variable expression, many parents are first diagnosed when a child is referred for evaluation. Approximately 50% of affected individuals have no affected parent and represent new mutations of the NF1 gene. Some parents of sporadically affected children may have germline mosaicism, so recurrence is possible, though rare.

Complications seen in NF1 are listed in **Table 1**.

Approach to Diagnosis

Diagnostic criteria for NF1 are given in **Box 2**. Neuroimaging is warranted in the case of neurological manifestations. MRI T2 hyperintensities **(Fig. 9)** occur in the majority of NF1 children, particularly in the brainstem, cerebellum and basal ganglia, but also in the hippocampi, thalami, and cerebral hemispheres. They are thought to represent abnormal myelination and gliosis. Echocardiogram, computed tomography of the abdomen and chest are required only if there is clinical suspicion of underlying involvement.

Management

Management of NF1 currently consists of surveillance, surgical treatment of progressive lesions, and genetic counseling.

BOX 2 Diagnostic criteria for neurofibromatosis type 1

NF1 is diagnosed in an individual fulfilling two or more of these criteria:

- Six or more café-au-lait spots measuring at least 5 mm before puberty or 15 mm after puberty
- Skin-fold freckling
- Two or more neurofibromas or one plexiform neurofibroma
- Two or more iris Lisch nodules
- Optic glioma
- Characteristic skeletal dysplasia (long bone or sphenoid wing)
- Affected first-degree relative.
Figures 9A to C Optic glioma in a 3-year-old child seen as thickened bilateral optic nerves (yellow arrow in A) in a T2W axial image of the brain. Compare it with normal optic nerves in B, yellow arrow. A also shows high signal with mass effect (red arrow) in the medial temporal lobe and pons suggestive of an astrocytoma. Neurofibromatosis type 1 can also have focal areas of high-signal intensity (FASI); seen in C (arrow), in bilateral globus pallidus and thalamus which cause no mass effect and are asymptomatic.
Source: Dr Sniya Sudhakar, Department of Radiodiagnosis, CMC, Vellore.

Table 1 System wise complications seen in neurofibromatosis type 1 (NF1)

Clinical feature	Age of onset (years)	Frequency
Neurological		
Aqueduct stenosis	Lifelong	1.5%
Chiari I malformation	Lifelong	1.5%
Glioma—brain and spinal cord	Lifelong	2–3%
Optic pathway glioma	Birth to 7	15%
Dysembryoplastic neuroepithelial tumor	Lifelong	< 5%
Cognitive impairment IQ < 70 (learning problems)	Birth	4–8%
Epilepsy	Lifelong	6–7%
Multiple sclerosis	Adulthood	< 5%
Cerebrovascular disease	Lifelong	2.5–6%
Peripheral nervous system		
Neurofibromatous neuropathy	Adulthood	1.3%
Eye		
Congenital glaucoma	Birth	0.7%
Bone		
Scoliosis	Birth to 18	10%
Bone dysplasia with or without pseudarthrosis	Birth to 3	2%
Osteoporosis	Childhood onwards	Not known
Short stature10th–25th percentile	Birth	30%
Cardiovascular disease		
Congenital heart disease—pulmonary stenosis	Birth	2%
Respiratory system		
Restrictive lung defect	Childhood onwards	< 5%
Gastrointestinal		
Stromal tumor	Adulthood	6%
Carcinoid	Adulthood	1.5%
Other tumors		
Pheochromocytoma	> 10	2%
Breast carcinoma	Adulthood in women < 50	Five-fold increase
Rhabdomyosarcoma	Lifelong	< 5%

Surveillance involves monitoring for complications and appropriate management of the same. Dermal neurofibromas can be removed by plastic surgery, use of the CO_2 laser, or electrodessication for cosmesis. Debulking of plexiform neurofibromas is sometimes necessary both for cosmesis and to relieve pressure on the airway or spine. Optic gliomas usually do not require treatment, but progressive symptomatic lesions usually are treated with chemotherapy (vincristine and carboplatin). Radiation therapy is best avoided in young children due to vascular complications and malignancies in the radiation field. Surgical removal of tumors are indicated when they cause pressure symptoms.

It is important to educate parents about the possibility of cognitive impairment and to provide neuropsychological assessment.

NEUROFIBROMATOSIS TYPE 2

Neurofibromatosis type 2 was considered a separate entity from the more common NF1 after a consensus conference at the National Institute of Health in 1987. With advanced neuroimaging, recent studies have suggested that the prevalence is approximately 1 in 60,000.

Etiology

Neurofibromatosis type 2 is an autosomal dominant condition with complete penetrance and variable expression characterized by multiple tumors of the nervous system and meninges as well as lesions of the eyes and skin. It results from a defect in the NF2 tumor suppressor gene situated on chromosome 22q11. Around 50–60% of patients have no family history and these represent new mutations.

Pathogenesis

The NF2 gene encodes the protein Merlin (moesin-ezrin-radixin-like protein), also called schwannomin. Merlin is localized to the cell membrane or cytoskeletal interface and influences downstream regulation of cell proliferation.

Clinical Features

Neurofibromatosis type 2 usually presents in early adulthood although milder phenotypes can present much later. Children more frequently present with visual disturbance, skin tumors or mononeuropathy whereas adults most often present with symptoms related to vestibular schwannomas.

Vestibular schwannomas **(Figs 10A and B)** are the commonest tumors to occur in NF2 and the clinical presentation is usually with hearing loss which starts unilaterally and becomes bilateral with time. The second most common tumor type encountered is meningioma which usually occurs on the cerebral convexities. Extramedullary spinal tumors like meningioma or schwannoma may also develop causing symptoms of a myelopathy.

Neurofibromatosis type 2 can also cause a neuropathy with no evidence of tumor infiltration. Children could present with a mononeuropathy affecting the facial nerve or unilateral wasted limb. In adulthood, 3–10% of patients may develop a severe polyneuropathy although up to 40% of adults show evidence of polyneuropathy on nerve conduction studies. The pathogenesis of the neuropathy is unclear but may be due to Schwann cell proliferation amongst the axons of nerves in the absence of frank tumor, the local toxic effect of tumor cells, or cellular dysfunction due to Merlin deficiency.

Up to 80% of them can have ophthalmological lesions in the form of posterior subcapsular cataract or cortical wedge opacities. Cutaneous lesions are few and include intracutaneous, plaque like lesions that are usually slightly hyperpigmented and may be covered in excess hair.

Approach to Diagnosis

Diagnostic criteria for NF2 are given in **Box 3**. Diagnosis is often delayed due to the paucity of cutaneous lesions. Depending on the clinical presentation, neuroimaging either of the brain or spinal cord will help identify the tumor. Genetic testing will detect 90% of mutations. Mosaicism can lead to segmental or unilateral involvement or milder disease.

BOX 3 Diagnostic criteria for neurofibromatosis type 2 (NF2)

Bilateral vestibular schwannomas or family history of NF2 plus
1. Unilateral VS or
2. Any two of: meningioma, glioma, neurofibroma, schwannoma, posterior subcapsular lenticular opacities
   Additional criteria: unilateral VS plus any two of: meningioma, glioma, neurofibroma, schwannoma, and posterior subcapsular opacities
   Or
   Multiple meningioma (two or more) plus unilateral VS or any two of: glioma, neurofibroma, schwannoma, and cataract

---
Figures 10A and B T2 drive sequence (A) and postgadolinium (B) axial images of the brain of an adult with bilateral vestibular schwannoma. The tumor on the right is large causing mass effect on the cerebellopontine angle. Compare it with the normal looking seventh eight nerve complex on the left which on the postgadolinium image (B) shows an enhancing lesion also suggestive of a schwannoma.
Source: Dr Sniya Sudhakar, Department of Radiodiagnosis, CMC, Vellore.

Management

Tumors associated with NF2 require surgical excision. Timing and extent of surgery depends on tumor size and involvement of adjacent structures. Stereotactic radiation therapy is also effective in treating tumors, but there is concern about later occurrence of malignant tumors in the radiation field. Recently bevacizumab, an antivascular endothelial growth factor (VEGF) monoclonal antibody that inhibits the angiogenic effects of VEGF has been used in the treatment of vestibular schwannomas. The neuropathy associated with NF2 is not responsive to any form of therapy.

STURGE-WEBER SYNDROME

Sturge-Weber syndrome (SWS) or encephalofacial angiomatosis is a sporadic disorder occurring due to early embryological malformation of the vascular system with a failure of the primitive cephalus venous plexus to regress and properly mature in the first trimester.

It is characterized by a facial capillary malformation (port-wine stain) in the ophthalmic distribution of the trigeminal nerve, with ipsilateral vascular glaucoma and vascular malformation of the eye, and vascular malformation of the brain (leptomeningeal angioma). The port-wine stain or facial angioma could be unilateral or bilateral and might extend to involve regions of the maxillary and mandibular divisions of the trigeminal nerve and in a few patients to the thorax, abdomen, and upper and lower limbs **(Fig. 11)**.

Neurological manifestations include epilepsy, focal neuro-logical deficit and psychomotor delay. Seizures which occur in 75–85% of patients are related to the leptomeningeal angioma. They are usually focal motor contralateral to the leptomeningeal angioma but can be of other types including infantile spasms. Focal neurological deficits include hemiplegia and hemianopia. Headaches and migraines are also common in SWS which may result from an increased vasogenic leakage of plasma and neuropeptides into the subarachnoid space. Ocular involvement may include eyelid hemangioma, glaucoma, conjunctival and episcleral hemangiomas, diffuse choroidal hemangiomas, and heterochromia of the irides.

MRI brain with gadolinium is the neuroimaging of choice which will show the leptomeningeal angioma and ipsilateral cerebral volume reduction **(Fig. 11)**. CT scan is superior to conventional MRI for demonstration of the characteristic calcification seen in SWS. It is seen as a double-lined gyriform pattern of calcification paralleling cerebral convolutions referred to as the railroad track sign **(Fig. 12)**.

Management of SWS involves anticonvulsants for seizures, symptomatic and prophylactic medications for headache, glaucoma treatment and laser therapy for facial angioma if they persist. Seizures are resistant to medications in about half the patients and they respond well to resective or disconnective epilepsy surgery like hemispherotomy.

OTHER NEUROCUTANEOUS DISORDER

A few other important neurocutaneous disorders are described in **Table 2**.
Figure 12 Plain CT brain of a child with Sturge-Weber syndrome (SWS) who underwent right posterior quadrantectomy for refractory epilepsy showing gyriform pattern of calcification over the right occipital lobe
Figure 11 Child with Sturge-Weber syndrome (SWS) showing the classic port-wine stain involving the left half of the face with contralateral hemiplegia. Postgadolinium axial images of the brain show ipsilateral leptomeningeal enhancement which represent the angiomatosis and underlying left cerebral hemiatrophy

Table 2 Other neurocutaneous disorders

Syndrome	Neurologic features	Non-neurologic features	Inheritance / Gene
Schwannomatosis	Multiple schwannomas	Subcutaneous schwannomas	Autosomal dominant, INI1/SMARCB1 on chromosome 22
Epidermal nevus syndrome (Fig. 13)	Hemimegalencephaly, epilepsy, intellectual disability, focal motor deficits	Linear verrucous lesions in cranio-facial distribution, precocious puberty, renal anomalies, colobomas	Sporadic
von Hippel-Lindau disease	Retinal, cerebellar and spinal hemangioblastomas	Tumors of the pancreas, kidney, epididymis, endolymphatic sac tumors	Autosomal dominant. VHL gene on chromosome 3p25-26
Neurocutaneous melanosis	Hydrocephalus, seizures, behavioral abnormalities	Giant hairy pigmented nevi, multiple hyperpigmented cutaneous nevi	Sporadic
Hypomelanosis of Ito (Fig. 14)	Intellectual disability, seizures, ocular features such as strabismus, myopia, optic nerve hypoplasia	Linear streaks or whorls of hypopigmentation along lines of Blaschko	Sporadic
Incontinentia pigmenti (Fig. 15)	Intellectual disability, seizures, pyramidal tract dysfunction, ocular abnormalities such as retinal detachment	Hyperpigmented brown macular lesions along lines of Blaschko that evolve through 3 stages of vesiculobullous lesions, verrucous lesions and the final brown lesions	X-linked dominant, NEMO gene

Figure 13 Linear verrucous lesions along the right side of neck and face in a child with epidermal nevus syndrome. T2 fluid attenuation inversion recovery (FLAIR) axial image of the brain shows flat and thick gyri involving the entire right cerebral hemisphere suggestive of hemimegalencephaly causing left hemiparesis and refractory epilepsy
Figure 14 Linear streak of hypopigmentation along the lines of Blaschko in a child with hypomelanosis of Ito

Figure 15 Extensive hyperpigmented brown macular lesions along lines of Blaschko, the final stage of cutaneous lesion in a child with incontinentia pigmenti

IN A NUTSHELL

1. Neurocutaneous disorders are diverse group of disorders with predominant involvement of the skin and nervous system tissues.
2. Tuberous sclerosis complex (TSC) is an autosomal dominant disease, characterized by hypomelanotic macules, facial angiofibroma, facial plaque, shagreen patches, seizures and intellectual disability.
3. Neurofibromatosis type 1 is autosomal dominantly inherited with 50% representing a new mutation. Diagnosis is clinical, based on presence of café-au-lait spots (CLSs) and neuro-fibroma.
4. Neurofibromatosis type 2 is characterized by bilateral vesti-bular schwannomas.
5. Sturge-Weber syndrome is a sporadic disorder with port-wine stain and cerebral leptomeningeal angiomatosis causing seizures and focal neurological deficits.
6. Diagnosis of all neurocutaneous disorders is based on clinical criteria and once diagnosed, requires periodic follow-up for evolution of complications.
7. Genetic testing is offered when individuals reach reproductive age and to first degree relatives of the affected individual.

Chapter 42.7
Hydrocephalus
Daljit Singh, Hukum Singh

Hydrocephalus is a clinical syndrome of raised intracranial pressure (ICP) with ventriculomegaly. It usually occurs from defective flow of cerebrospinal fluid (CSF) or rarely from excessive secretion. It should be differentiated from ventriculomegaly which is a radiological condition of large ventricle and usually asymptomatic. However both these terminologies are often interchanged. It is important to differentiate between two as hydrocephalus requires treatment where ventriculomegaly alone may not.

The first description of hydrocephalous was made by Rhazes (850-923 AD). The major evolution in the treatment of hydrocephalus happened with development of shunt procedures and later the third ventriculostomy. Dandy proposed coagulation of choroid plexus in nonobstructive hydrocephalus in 1919 and third ventriculostomy for obstructive hydrocephalus in 1922. Dandy father of neuroendoscopy, attempted endoscopic fulguration of choroid plexus. Mixter did first third ventriculocisternostomy in 1923.

The reported incidence of hydrocephalus ranges from 0.2 to 0.5/1000 births with a higher incidence has been reported in the offspring of elderly primiparous mothers.

ETIOLOGY

Hydrocephalus can be categorized as congenital and acquired **(Table 1, Figs 1 and 2)**. Causes of hydrocephalus can be classified as per the age of onset of hydrocephalus:

- *Premature infants* Posthemorrhagic hydrocephalus is seen as a sequel of intraventricular or germinal matrix hemorrhage. It leads to fibrosing arachnoiditis, meningeal fibrosis and subependymal gliosis altering the physiology of CSF flow.
- *Full-term infant* Aqueductal stenosis, Dandy-Walker malformation, tumors, Arachnoid cyst, vein of Galen malformation, Chiari malformation and intrauterine infection, and post-tubercular hydrocephalus.
- *Older children* Tumors, trauma and infection can lead to hydrocephalus due to obstruction in CSF flow along its pathway, post-tubercular hydrocephalus and brain tumors.

Functional Classification

Dandy and Blackfan described the functional division of hydrocephalus, i.e., communicating (nonobstructive) and noncommunicating (obstructive). Obstructive hydrocephalus refers to obstruction to the CSF flow within the ventricular system, such as blockage at the foramen of Monro (asymmetrical ventriculomegaly), aqueduct of Sylvius or the basal foramen of Luschka and Magendie **(Fig. 3)**. Communicating hydrocephalus on the other hand results due to obstruction outside the ventricular system, at the level of subarachnoid space or the arachnoid villi. It results due to poor absorption of CSF.

Table 1 Etiology of hydrocephalus

Congenital	Acquired
1. Aqueductal obstruction/stenosis—CSF flow is impaired when cross sectional area of aqueduct < 0.25 mm	1. Tumors and cysts obstructing the CSF pathway **(Figs 1 and 2)**
2. Arnold-Chiari malformation	2. Posterior fossa tumors

Figure 4 Cast of ventricle depicting ventricle and flow of CSF pathway

Besides, there are certain special categories of hydrocephalus, e.g., hydrocephalus in utero, external hydrocephalus, double compartment hydrocephalus, multicystic hydrocephalus, unilateral hydrocephalus, arrested hydrocephalus, slit ventricular system and hydrocephalus *ex vacuo*.

PATHOPHYSIOLOGY

Normal CSF production is 0.35 mL/min. Capacity of lateral and third ventricle is 20 mL. Total CSF volume is 120 mL. ICP rises if production of CSF is more than absorption.

Cerebrospinal fluid is produced in the lateral ventricle by the choroid plexus. The production of CSF is an active process and is regulated by osmotic gradient as well as by enzyme carbonic anhydrase. CSF flows from lateral to third ventricle via foramen of Monro. From third ventricle, CSF flow to fourth ventricle via aqueduct of Sylvius. Length of aqueduct of Sylvius is usually 8–12 mm in length. Fourth ventricle is holds only small amount of CSF and has four opening for CSF to flow from it. A pair laterally placed foramen of Luschka, single medially placed foramen of Magendie and a central opening which leads into central canal of spinal cord. The CSF after flowing out from fourth ventricle ascends up and is absorbed by the arachnoid granulations present along the midline by superior sagittal sinus. The entire concept is known as bulk flow of CSF which was proposed by Dandy **(Fig. 4)**. CSF is also absorbed by capillaries in the subarachnoid space and 2, 7, 9 and 10th cranial nerves.

The flow of CSF inside as well as outside the ventricle is regulated by the cardiac cycle. The flow is outside the ventricle in systole and toward the ventricle in diastole. This pulsatile flow of CSF has added newer understanding in the pathogenesis of hydrocephalus **(Fig. 5)**.

CLINICAL FEATURES

The presentation of hydrocephalus is variable. It depends upon the age of patients **(Table 2)**, ability to withstand the change in the volume of CSF fluid and pulsatility of blood vessels. The clinical features are also classified as acute and chronic hydrocephalus. An increase in size of head circumference by more than 2 cm in any month is a sign of progressive hydrocephalus. In congenital hydrocephalus the infant may be normal at birth and shows subsequent enlargement of head especially at the age of nine month and at three year.
Figure 5 Pulsatile flow of CSF guided by cardiac cycle

Table 2 Clinical features of hydrocephalus according to age

Age	Symptoms	Sign
Infants	1. Poor feeding 2. Vomiting 3. Reduced activity 4. Drowsiness	1. Head enlargement 2. Dilated scalp vein 3. Tense fontanelle 4. Failure of upward gaze 5. Sunset sign 6. Increased limb tone
Children	1. Slowing of mental capacity 2. Headache 3. Vomiting 4. Vision deterioration 5. Drowsiness	1. Papilledema 2. Failure of upward gaze 3. Unsteady gait 4. Cracked pot sign 5. Large head

Acute Hydrocephalus

Acute hydrocephalus will present with headache, vomiting, nausea, respiratory difficulties (Cheyne-Stoke) and papilledema. Beside children may present with wide tense fontanels, irritability, lack of interest, and rejection of food. Neurogenic pulmonary

edema can be associated fatal condition due to refractory raised ICP. Decerebration and decortication can happen if hydrocephalus remains untreated. Altered sensorium or loss of consciousness may be terminal in such cases.

Chronic Hydrocephalus

Chronic hydrocephalus presents with enlarged head, percussion of head produces the classic cracked pot sound (McEwan sign), restricted upward gaze (Parinaud syndrome). Setting sun sign refers to weakness of upward gaze is caused when the dilated suprapineal recess compresses the quadrigeminal plate. In addition, there can be sutural diastasis, visible scalp vein and impaired mentation **(Fig. 6)**. Many a time the only presentation can be generalized seizure which is ischemic in origin. Bradycardia, hypertension, arrhythmia and asystole can be associated finding. False localizing sign, e.g., unilateral or bilateral 6th nerve palsy are not uncommon. Hydrocephalus may be associated with neural tube defects, chiari malformation, cleft palate and congenital heart disease, Dandy-Walker syndrome, primary or secondary aqueductal stenosis, neonatal infections and intracranial brain tumors.

Differential diagnosis Causes of enlarged head include familial macrocephaly, hydranencephaly, subdural effusion, rickets, and megalencephaly.

INVESTIGATIONS

The aim of investigation in hydrocephalus is to know the type of hydrocephalus, flow of CSF and extent of anatomically visible brain. These have implications in deciding type of treatment to be offered and likely functional and psychological recovery.

X-ray Skull

Plain X-ray skull is of limited value. Suture widening, erosion of posterior clinoids, silver beaten appearance and ballooning of sella can be the evidence of chronic raised ICP.

CT Head

The CT scan head provide adequate information about etiology and type of hydrocephalus. In obstructive hydrocephalus, both lateral and third ventricles are dilated. In communicating hydrocephalus there is generalized enlargement of ventricle. In addition there will be presence of CSF in subarachnoid spaces as there is defective

Figure 6 A child with hydrocephalus, with sun set sign and distended veins on scalp

absorption of CSF in such cases. Presence of periventricular lucencies and absent sulci are indicator of raised ICP and are to be considered as warning sign **(Fig. 7)**. There can be unilateral dilatation of ventricle in obstructed foramen of Monro **(Fig. 8)**, dilatation of lateral ventricle and third ventricle in aqueductal stenosis (triventriculomegaly), dilatation of lateral ventricle, third ventricle and fourth ventricle due to outlet obstruction **(Fig. 9)**. The normal bifrontal width of lateral ventricle is on average 30% of brain width at this level. When this ratio (Evans ratio) is more than 30%, it is suggestive of hydrocephalus **(Fig. 10)**.

MRI Brain

MRI scanning shows the extent of dilatation of ventricle, site and nature of block. Midsagittal scan reveals the type of aqueductal stenosis and length of obstruction. The periventricular and white matter changes are better seen in the MRI in comparison to CT scan. Cine mode MRI can show the flow of CSF via aqueduct and is helpful in establishing aqueductal stenosis and in follow-up of patency of stoma after the endoscopic third ventriculostomy (ETV).

Ultrasonography

Ultrasonography through anterior fontanelle can demonstrate ventricular enlargement in infants but provides less precise information than CT scanning. It is the procedure of choice for imaging fetal brain.

TREATMENT

The optimal treatment of hydrocephalus may vary with etiology, type of hydrocephalus and extent of emergency involved. The medical treatment shall not be prolonged for more than couple of days unless there is definite improvement with it. Many a time the symptoms of hydrocephalus are refractory to treatment. Under such situation the other causes of nonimprovement should be addressed. These include presence of vasculitis, infarction, demyelination, cerebritis, tuberculoma, ventriculitis or abscess in the brain.

Medical Treatment

Acetazolamide (Diamox), a carbonic anhydrase inhibitor reduces the CSF production. It is given as 25 mg/kg/day divided in dose, can be increased up to 100 mg/kg/day with a strict watch on electrolytes and arterial blood gas (ABG). Acetazolamide may act for noncommunicating hydrocephalus, post-tubercular hydrocephalus and as a temporary relief prior to surgical intervention. Frusemide 0.5 mg/kg and mannitol 0.25–0.5 mg/kg q 6h act as additional agents to lower intracranial temperature (ICT). These have no role to play on decreasing size of ventricles. Steroids (dexamethasone 0.25–1 g/kg/day) can be recommended for a short time in postinfective hydrocephalus just to dissolve the exudates in prepontine and subarachnoid spaces.

Surgical Interventions

Lumbar Drainage

Tapping of CSF from the spinal subarachnoid space can help in relieving ICP particularly in communicating hydrocephalus. Post-tapping headache and tonsillar herniation can be sequelae of such procedure. Lumboperitoneal shunt usage is gradually decreasing.

Ventriculoperitoneal Shunt

The most accepted surgical procedure in the treatment of hydrocephalus is ventriculoperitoneal shunt (VP shunt). The
Figure 7 Presence of periventricular lucency indicating raised intracranial pressure
Figure 8 Asymmetrical ventricle in obstructed foramen of Monro

peritoneal end can be inserted in peritoneal cavity through open or laparoscopic techniques. The most commonly used VP shunts are Chhabra, Upadhyay and currently flow regulated shunt devices that sense the flow through a magnetic strip. The CSF from the ventricle is drained via a silicon tube into abdomen. A subcutaneous tunnel carries the shunt from the ventricle to abdomen. VP shunt is a standard surgical treatment. There are several complications that can be associated with it, e.g., infection, shunt obstruction, migration **(Fig. 11)** bleeding, ascites and subdural effusion. The success rate of VP shunt is 70–90%. The prognosis depends mainly on the extent of damage to the brain before the insertion of shunt and associated anomalies. Provided treatment precedes irreversible brain damage, results are good with most children attaining normal IQs.

Ventriculoatrial Shunt
Ventriculoatrial shunt is particularly useful in the presence of abdominal disease. VA shunt leads to glomerulonephritis and endocarditis hence has been abandoned by most neurosurgeons.

Endoscopic Third Ventriculostomy
Endoscopic third ventriculostomy is an excellent minimally invasive procedure for hydrocephalus in which internal shunting is done within ventricular system. An osteomy is made along the floor of third ventricle which drains CSF in prepontine cistern, bypassing aqueduct of Sylvius obstruction. The success rate varies from 70% to 90% depending upon the initial cause of hydrocephalus, especially in aqueductal stenosis. Rescue ETV is indicated in repeated shunt failure. Complication following ETV in a large series was found 8–10%. The fatal complications are usually
Figure 9 Fourth ventricle outlet obstruction shows dilated fourth ventricle with large foramen of Luschka

Figure 11 Migrated ventricular shunt per rectal

rare but can happen with rupture of basilar artery or its branch. Damage to fornix, thalamus, septal and thalamostriate vein can result during surgery and may cause neurological deficit.

IN A NUTSHELL

1. Hydrocephalus is a clinical syndrome of raised intracranial pressure with ventriculomegaly.
2. Aqueductal stenosis, Chiari malformation, and Dandy-Walker syndrome are the main causes of congenital hydrocephalus.
3. Tubercular meningitis and intracranial tumors are predominant causes of acquired hydrocephalus in children.
4. Acute hydrocephalus presents with headache, vomiting, nausea, respiratory difficulties and papilledema. Chronic hydrocephalus presents with enlarged head, McEwan sign, restricted upward gaze, and setting sun sign.
5. Familial macrocephaly, hydranencephaly, subdural effusion, rickets, and megalencephaly should be considered in the differential diagnosis.
6. Neuroimaging is the mainstay of diagnosis.
7. Medical management includes acetazolamide, mannitol, and furosemide. Ventriculoperitoneal shunt is the most common surgical procedure for relief of hydrocephalus.

Chapter 42.8
Seizures and Epilepsy
Puneet Jain, Lakshminarayanan Kannan

Seizures are the most common neurological problem encountered in children and are often a frightening experience for the parents or caretakers. Epilepsy affects 0.5–1% of the population in India according to various estimates. Majority of epilepsies have onset in childhood.

Seizure is a symptom of central nervous system (CNS) dysfunction due to any cause. Seizures may occur in a myriad of conditions ranging from simple provoking factors like sleep deprivation, drug toxicity and drug withdrawal to CNS insults of any cause. Occurrence of seizures is necessary but per se is not sufficient for the diagnosis of epilepsy. Epilepsy is a condition characterized by the occurrence of recurrent unprovoked seizures.

Epilepsy is not a single disease. It is a heterogeneous group of diseases of diverse etiologies. Epilepsy is a clinical diagnosis. There is no investigation that confirms the diagnosis of epilepsy. Electroencephalogram (EEG), at best, supports the clinical diagnosis of epilepsy. A normal EEG does not rule out epilepsy and at the same time an abnormal EEG by itself is not diagnostic of epilepsy.

DEFINITIONS

An *epileptic seizure* be defined in as *'a transient occurrence of signs and/or symptoms due to abnormal excessive or synchronous neuronal activity in the brain'* [*International League Against Epilepsy* 2005 (ILAE 2005)]. Operationally, these signs or symptoms may include sudden and transitory abnormal phenomena such as alterations of consciousness, or involuntary motor, sensory, autonomic, or psychic events perceived by the patient or an observer.

Epilepsy is defined as *a disorder characterized by an enduring predisposition to generate epileptic seizures and by neurobiologic, cognitive, psychological and social consequences of this condition. The definition requires the occurrence of at least one epileptic seizure* (ILAE 2005). This is a conceptual definition. For epidemiological purposes, epilepsy is said to occur if there are at least two unprovoked seizures occurring more than 24 hours apart. This definition excludes single cluster occurring within a 24-hour period, single episode of status epilepticus, febrile seizures, neonatal seizures, and acute symptomatic (or provoked) seizures.

Acute symptomatic (or provoked) seizures occur in close temporal association with an acute systemic, metabolic, or toxic insult or in association with an acute CNS insult (infection, stroke, trauma, intracerebral hemorrhage, or acute alcohol intoxication or withdrawal). Seizures occurring within 7 days of cerebrovascular disease, cerebral hypoxia, CNS infection and traumatic brain injury are classified as acute symptomatic. Similarly, seizures occurring in association with tuberculoma or brain abscess are acute symptomatic when occurring during the treatment. Seizures in a child with neurocysticercosis are acute symptomatic if occurring during the transitional or degenerative phase of the parasite (on neuroimaging). If they occur with the viable parasites (acute phase) or calcified granuloma (calcified phase), the seizures are traditionally classified as unprovoked. Seizures in association with arteriovenous malformations are acute symptomatic during the acute hemorrhage. The documented metabolic abnormality on blood sample (e.g., hypoglycemia, hypocalcemia, hyponatremia, etc.) should be within 24 hours of the seizure for the seizure to be classified as acute symptomatic seizure in association with that metabolic condition.

CLASSIFICATION

The most recent classification system was proposed in 2010 by Berg et al. Presented here is a classification of broad categories of seizures and epilepsies **(Boxes 1 and 2)**. The classification of epilepsies incorporates the ictal phenomenology, seizure type, epilepsy syndrome, underlying etiology, co-morbidities and impairments.

Epilepsy Syndrome

It is a complex of clinical features, signs, and symptoms that together define a distinctive, recognizable clinical disorder. These are distinctive disorders identifiable on the basis of a typical age onset, specific EEG characteristics, seizure types, and often other features which, when taken together, permit a specific diagnosis. The diagnosis in turn often has implications for treatment, management, and prognosis.

EPIDEMIOLOGY

The overall incidence of childhood epilepsy is approximately 40 cases per 100,000 children per year in the developed countries. The highest incidence rate is observed in infancy with a peak in the first week of life with subsequent decline with age. The reported prevalence rate varies within countries and tends to increase with age. In India, the reported prevalence rates are 5 to 22 per 1,000. The prevalence rates are believed to be higher in developing countries due to high incidence of adverse perinatal events, CNS infections including parasitosis and head trauma.

The overall risk of recurrence of seizure is around 40% after first seizure and 80% after the second seizure. Majority of recurrences will occur within the first 6 months (around 75%). The presence of a remote symptomatic cause, focal seizures, intellectual handicap and EEG abnormalities increase the risk of seizure recurrence. Most children do not have many seizures. Less than one-third of children with focal or convulsive seizures will have more than or equal to 10 seizures in first 10 years after diagnosis.

CLINICAL EVALUATION

The history and physical examination are the basic tools in the evaluation of a child with seizure(s). The goals of the clinical

---

BOX 1 Classification of seizures

Generalized seizures

Tonic–clonic (in any combination)

Absence (typical or atypical)

Myoclonic

Clonic

Tonic

Atonic

Focal seizures

Without impairment of consciousness or awareness (old term: simple partial seizure)

With observable motor or autonomic components

Involving subjective sensory or psychic phenomena only (aura only)

With impairment of consciousness or awareness (old term: complex partial seizures)

Evolving to a bilateral, convulsive seizure (old term: secondary generalized seizure)

BOX 2	Epilepsy/electroclinical syndromes arranged by age at onset* (Berg et al 2010)

Neonatal period

  Benign familial neonatal epilepsy (BFNE)

  Early myoclonic encephalopathy (EME)

  Ohtahara syndrome

Infancy

  Epilepsy of infancy with migrating focal seizures

  West syndrome

  Myoclonic epilepsy in infancy (MEI)

  Benign infantile epilepsy

  Benign familial infantile epilepsy

  Dravet syndrome

  Myoclonic encephalopathy in nonprogressive disorders

Childhood

  Febrile seizures plus (FS+) (can start in infancy)

  Panayiotopoulos syndrome

  Epilepsy with myoclonic atonic (previously astatic) seizures

  Benign epilepsy with centrotemporal spikes (BECTS)

  Autosomal-dominant nocturnal frontal lobe epilepsy (ADNFLE)

  Late onset childhood occipital epilepsy (Gastaut type)

  Epilepsy with myoclonic absences

  Lennox-Gastaut syndrome

  Epileptic encephalopathy with continuous spike-and-wave
    during sleep (CSWS)

  Landau-Kleffner syndrome (LKS)

  Childhood absence epilepsy (CAE)

Adolescence – Adult

  Juvenile absence epilepsy (JAE)

  Juvenile myoclonic epilepsy (JME)

  Epilepsy with generalized tonic-clonic seizures alone

  Progressive myoclonus epilepsies (PME)

  Autosomal dominant epilepsy with auditory features (ADEAF)

  Other familial temporal lobe epilepsies

Less specific age relationship

  Familial focal epilepsy with variable foci (childhood to adult)

  Reflex epilepsies.

*Certain syndromes are often referred to as epileptic encephalopathies (P. 2101)

evaluation are confirmation of the paroxysmal event as epileptic, defining the semiology and establishing the etiology and identification of any epilepsy syndrome. Questions to be answered while evaluating a child with seizures:

- Is it a seizure or a seizure mimic (e.g. syncope, breath holding spell, etc.)?
- Is it provoked or unprovoked?
- Is the seizure focal or generalized?
- What is/are the seizure type(s)? (myoclonic, absence, atonic, etc.)
- Are there any co-morbidities? (e.g., mental retardation, cerebral palsy, etc.)

- What is the likely epilepsy syndrome?
- What is the likely etiology?

Confirmation of the Paroxysmal Event as *Epileptic*

The diagnosis of seizures or epilepsy is predominantly based on the clinical history. It often requires detailed and meticulous and patient questioning of the parents or anybody else (e.g., school teacher) who has witnessed the event. Establishing a paroxysmal clinical event as an epileptic seizure is a vital first step towards the correct diagnosis of epilepsy. Ruling out a nonepileptic paroxysmal event is important. These seizure mimickers are detailed in chapter on nonepileptic paroxysmal disorder.

The parent or caregiver may be asked to demonstrate or imitate the event. If necessary, the doctor may also demonstrate the seizure semiology for the parent or caregiver to recognize. Home videos recorded by parents using mobile phones are very useful tool in this regard. There are five important aspects to the eye witness account of any paroxysmal event. These are aura (any warning symptom?), the start (how did the event start?), the progression (how did it progress?), the associated features (what are the accompaniments?), the postictal manifestations (what happened just after the end?). This systematic account is of immense help not only in ascertaining any event as seizure or not but also in classifying seizure as focal or not.

To Classify Seizures as Focal or Generalized

The following features indicate focal origin of seizures: aura, focal involvement early in the seizure (before secondary generalization), tonic deviation (or version) of head or eyes to one side, asymmetric involvement of limbs during any part of a seizure, presence of autonomic features like flushing, change in breathing, immediate postictal focal functional impairment (Todd's paresis).

Generalized Seizures

Generalized tonic-clonic seizure Primary generalized tonic-clonic seizure *(GTCS)* may arise de novo or follow clusters of myoclonic jerks or absences (seen in idiopathic generalized epilepsies). GTCS starts with opening of eyes, tonic deviation of head and eyes (±) followed by a *tonic phase* characterized by sustained contraction of all skeletal muscles. This phase may be characterized by forced closure of the mouth, tongue biting, *epileptic cry* and cyanosis. The tonic phase ends with a *vibratory tremor* usually involving distal and facial muscles. This is followed by *clonic phase* with continuous clonic jerks of facial, trunk and limb muscles. Its duration is variable with decreasing force, amplitude and frequency of jerks with time. The *recovery phase* starts with the cessation of the clonic jerks and is characterized by unresponsiveness, bronchial secretions, urinary and rarely fecal incontinence. There is gradual recovery. Significant autonomic changes occur from the onset of GTCS with peak at the end of the tonic phase and subsequent recovery. In children, tonic phase may be longer than the clonic phase.

Generalized tonic seizures They are characterized by sustained muscular contractions (> 2 s) only without clonic components.

Generalized clonic seizures They are characterized by rhythmic clonic convulsions only. *Myoclonus*: It is a sudden brief (< 100 ms) involuntary shock-like contraction of muscle(s) or muscle groups of variable topography. They may be focal, segmental, multifocal or generalized. They may be physiological, epileptic (cortical) or non-epileptic (sub-cortical).

Epileptic spasms The term epileptic spasm is preferred to *infantile spasm* as they can occur in any age. Spasms are sudden and brief (0.2–2 s) tonic contractions of the axial and proximal limb muscles with abrupt onset and termination. They may occur in clusters or isolated. They may be flexor, extensor or mixed; symmetrical or

asymmetrical. Spasms may be subtle appearing as facial grimacing, isolated eye movements, yawning, gasping or transient focal motor activity. The spasms are accompanied by various autonomic changes. They may be followed by cry or laughter. Epileptic spasms predominantly occur on awakening or in awake state and rarely occur in sleep.

Tonic seizures It involves sudden loss of muscle tone (1–2 s) without preceding myoclonic or tonic event, involving head, jaw, trunk or limb muscles. It may manifest as only head drop to a fall. Consciousness is usually preserved.

Absence seizures Typical absences are brief seizures with abrupt onset and termination lasting for 5–20 s, usually occurring multiple times in a day. They are characterized by variable impairment of consciousness (inconspicuous, mild, moderate or severe) and classical generalized 3 Hz spike-wave-discharges on ictal EEG. They are usually precipitated by hyperventilation. Typical absence seizures may be associated with myoclonic components involving eyelids, eyebrows, corner of the mouth and rarely nostrils lasting for a brief time usually at the onset of the seizure. Automatisms (lip licking, smacking, swallowing, fumbling with clothes, etc.) and autonomic disturbances are common.

Atypical absences are usually longer with inconspicuous onset and termination. The impairment in consciousness is usually variable and subtle with significant tone abnormalities and gradual postictal recovery. They usually occur in children with severe psychomotor retardation or learning disabilities and are accompanied by other seizure types.

Drop attack is a peculiar ictal phenomenology seen predominantly in children, and occurs with epileptic spasms, tonic, atonic, myoclonic seizures and atypical absences. Drop attacks can be very dramatic and injurious at times.

Focal Seizures

Without impairment of consciousness or awareness (simple partial seizure) This a type of focal seizures where the patient retains awareness and responsiveness to the environmental cues appropriately. There may or may not be any motor automatisms.

With observable motor or autonomic components Autonomic features may be in the form of pallor, sweating, flushing, increased or rarely decreased heart rate or change in respiration. Motor component may include focal tonic or dystonic posture or clonic jerking.

Establishing the Etiology and Identification of Epilepsy Syndrome

Etiology and syndromic diagnosis of epilepsies are vital for management and prognosis. Important medical history includes:
- Age of onset of seizures
- Seizure types, evolution
- Previous history of febrile seizures (simple/complex)
- Associated features
- Developmental trajectory: normal, stagnation, regression
- Pointers towards inborn error of metabolism **(Table 1)**
- Comorbidities
- Detailed birth and peri-/antenatal history
- Previous history of trauma or CNS infection
- Family history

Clinical examination should include anthropometry, dysmorphism, neurocutaneous features and detailed neurological and systemic assessment. It is also important to screen for various comorbidities like tone abnormalities, contractures, vision or hearing deficits, dental hygiene, difficulty in feeding

Table 1 Affected genes in epilepsy

Epilepsy	Genes affected
Benign familial neonatal seizures	KCNQ2, KCNQ3
Benign familial neonatal-infantile seizures	SCN2A
Genetic epilepsy with febrile seizures plus (GEFS)	SCN1A, SCN1B, GABRG2
Early-onset absence epilepsy	SLC2A1
Juvenile myoclonic epilepsy	EFHC1, GABRA1
Autosomal dominant nocturnal frontal lobe epilepsy	CHRNA4, CHRNB2, CHRNA2
Autosomal dominant partial epilepsy with auditory features	LGI1
X-linked infantile spasms/Rett syndrome	CDKL5/STK9
Ohtahara syndrome	ARX, STXBP1
Epilepsy and mental retardation limited to Females	PCDH19
Dravet syndrome	SCN1A

or malnutrition, sleep disorders and behavioral disorders, and adverse effects of the antiepileptic drugs (AEDs).

GENETICS OF EPILEPSY

In recent years, there are newer genetic mutations identified in the causation of epilepsy. This has many implications not only for diagnosis but also for the treatment modalities used and the prognosis. For example, it is well known now that lamotrigine causes worsening of seizures in Dravet syndrome. Thus, whenever SCN1A spectrum is suspected lamotrigine should be avoided. There are panel of gene tests commercially available for epileptic encephalopathy and other epilepsy syndromes. **Table 1** lists some of the examples of epilepsy syndromes and the respective genes affected.

ROLE OF EEG

When used judiciously, EEG is the single most useful tool in managing patients with epilepsy optimally. EEG can only support a clinical diagnosis of epilepsy when it is abnormal but cannot exclude epilepsy when it is normal. EEGs may be normal in some patients with epilepsy (e.g., early EEGs in Dravet's syndrome, insular seizures, frontal lobe epilepsy and simple partial seizures including epilepsia partialis continua).

On the other hand EEG abnormality per se does not mean that the patient has epilepsy. A patient with *genetic trait* has an epileptiform EEG but does not necessarily always manifest the disease. EEG abnormality may be seen in first degree relatives with epilepsy. As it is true for many clinical situations, a patient needs to be treated as a whole and not the EEG. There are few exceptions, wherein one needs to aggressively treat EEG abnormalities such as hypsarrhythmia, epileptic encephalopathy, electrical status epilepticus in slow wave sleep (ESES) even if the patient has only few clinical seizures. Indications of EEG are listed in **Box 3**.

Role of prolonged video EEG monitoring Long-term video-EEG monitoring is very essential part of epilepsy presurgical evaluation. Clinical situations where video EEG proves useful are listed below: To characterize events (e.g., nocturnal frontal lobe epilepsy versus parasomnia).
- Gold standard for diagnosing psychogenic nonepileptic events
- To characterize semiology and to classify epilepsy syndrome
- Presurgical evaluation (to define ictal onset zone).

ROLE OF NEUROIMAGING IN EPILEPSY

In cases of new-onset focal seizures, imaging abnormality can be expected in up to 50% of cases. But of these, only in 15–20% of cases imaging provides useful information on etiology of the underlying condition. Imaging results potentially altered immediate medical or surgical management in a minority of these patients (2–4%).

Thus, neuroimaging should be utilized judiciously for epilepsy patients in resource limited settings like ours. Ordering neuroimaging when it is not indicated [as in cases of childhood absence epilepsy (CAE)] is clear wastage of resources and time. There are four broad goals for imaging a patient with epilepsy: (1) to identify patients in whom alteration in medical or surgical management would ensue with imaging results, (2) to localize a lesion (site of seizure origin), (3) to establish etiology of epilepsy, (4) to determine prognosis. Imaging is not indicated in CAE, idiopathic generalized epilepsy, benign childhood epilepsies and when genetic syndromes (Down syndrome, Angelman syndrome, etc.) are suspected. Indications for neuroimaging are listed in **Box 4**. MRI is the imaging modality of choice whenever neuroimaging is indicated in epilepsy. CT scan may be used an initial investigation in resource-limited settings, where intracranial granulomas (neurocysticercosis) are common causes of seizures.

FIRST UNPROVOKED SEIZURE

An unprovoked seizure is *a seizure or a cluster of seizures occurring within 24 hours in a child older than 1 month of age, occurring in the absence of precipitating factors*. Thus, a seizure flurry occurring within 24 hours with return to baseline between seizures is typically considered to represent as a first seizure. It is also important to note that the first unprovoked seizure will be status epilepticus in 10–20% cases. The incidence of unprovoked seizures ranges from 50 to 70 per 100,000 with higher prevalence in children younger than 1 year of age.

The investigations must be individualized. If the seizure appears focal, or secondarily generalized, neuroimaging (MRI or CT) is appropriate. If the patient has absence seizures, or the history is very suggestive of rolandic epilepsy, EEG is the investigation of choice.

EPILEPTIC ENCEPHALOPATHIES

The term *epileptic encephalopathy* refers to a group of disorders in which the unremitting epileptic activity contributes to progressive neurological dysfunction. This cannot be explained by the

underlying etiology alone. The underlying etiology is diverse. Their clinical and electroencephalographic (EEG) features reflect the specific age-related epileptogenic reaction of the immature brain. The various syndromes of epileptic encephalopathy are tabulated in **Box 5**.

Early Infantile Epileptic Encephalopathies

This group of disorders comprises of Ohtahara syndrome or early infantile epileptic encephalopathy (EIEE) and early myoclonic encephalopathy (EME).

Ohtahara syndrome is a catastrophic epilepsy with onset ranging from intrauterine period to 3 months of age. The defining seizure types are frequent *tonic spasms* that occur in both sleep and wakeful states. Besides these, partial and rarely myoclonic seizures may be observed. The inter-ictal EEG shows burst suppression pattern with no sleep-wake differentiation.

The underlying causes are heterogeneous. The majority of cases are attributable to static structural brain lesions such as focal cortical dysplasia, hemimegalencephaly, and Aicardi syndrome. Few genetic mutations have been described but these are not specific for Ohtahara syndrome.

Early myoclonic encephalopathy presents within first 3 months of age and mostly within the neonatal period. Fragmentary erratic myoclonia, partial seizures and less frequently tonic spasms are seen. The interictal EEG shows burst suppression pattern more prominent during the sleep. The etiologies include inborn errors of metabolism (such as nonketotic hyperglycinemia, organic acidemias, Menkes disease, Zellweger syndrome), genetic factors and rarely structural abnormalities.

The seizures in these syndromes are often drug-refractory. The ketogenic diet has been tried with limited success. Neurosurgery is sometimes favorable in selected cases of cerebral malformations. The prognosis is uniformly poor with survivors left with severe psychomotor retardation. There may be *age-dependent evolution* in Ohtahara syndrome to West syndrome and then subsequently to Lennox-Gastaut syndrome (LGS).

West Syndrome

West syndrome was first described by W.J. West in 1841 and is characterized by epileptic spasms or *salaam attacks*, hypsarrhythmia/variants on EEG and developmental arrest or regression. West syndrome is one of the age-related epileptic encephalopathy with a typical onset is between 3 months and 12 months of age. The epileptic spasms are clusters of sudden, brief diffuse or fragmented, tonic contractions of axial and limb muscles. Spasms are longer than myoclonic jerks and shorter then tonic seizures in duration. The spasm clusters may be accompanied by cry, laughter or autonomic changes. It may be flexor (most common), extensor, mixed or subtle. They usually occur on arousal and in alert states.

The etiology is diverse. West syndrome has been classically classified into symptomatic (identifiable neurological insult), cryptogenic (probably symptomatic but with no known etiology)

and idiopathic (normal premorbid development and unknown etiology) forms. The classification as per new ILAE classification is shown in **Box 6**. Thus, a thorough clinical evaluation followed by appropriate neuroimaging and genetic and metabolic work-up is warranted in a child with West syndrome.

Epileptic spasms can occur with or without hypsarrhythmia in EEG. When infantile spasms are associated with hypsarrhythmia and development arrest or regression, this fulfills the criteria for West syndrome. Hypsarrhythmia is a specific EEG pattern with chaotic background activity and very high amplitude sharp and spike-slow waves over bilateral posterior quadrants. Hypsarrhythmia is an essential part of the diagnosis of West syndrome.

Infantile spasms require different approach to treatment compared to other seizures occurring in this age group. Hormonal therapy [adrenocorticotrophic hormone (ACTH) or oral prednisolone] is the treatment of choice for short-term treatment of epileptic spasms. Vigabatrin is a second-line drug except in children with tuberous sclerosis complex where it is the preferred drug. Recent literature also supports an early trial of oral pyridoxine. Drugs like phenytoin, carbamazepine may cause worsening of spasms and phenobarbitone is mostly not effective. The ketogenic diet has also shown to be beneficial. Neurosurgery may be warranted in refractory selected cases.

The prognosis is guarded and is governed by the underlying etiology and the timeliness of specific treatment. A common mistake that delays initiation of specific therapy is to treat epileptic spasms with phenobarbitone, sodium valproate and other AEDs that are not very effective in this context. The earlier the condition is recognized and the specific therapy started the better is the neurodevelopmental outcome. The affected children are left with variable psychomotor retardation, epilepsy or behavioral disorders.

Dravet Syndrome

It was first described by Charlotte Dravet in 1978 as severe myoclonic epilepsy of infancy (SMEI). The onset is usually between 5 months and 8 months of age with frequent, prolonged febrile unilateral clonic convulsions with alternating pattern in a previously normal child. Non-febrile prolonged GTCSs may also be present. This stage is followed by emergence of multiple seizure types (myoclonic, atypical absences and complex focal seizures) which frequently progress to status epilepticus and associated severe neurological deterioration. The initial development is normal in infancy and the development arrest or regression starts in 2–4 years of age. The relentless progression stops at around 10–12 years of age with decrease in seizure frequency and persisting neurologic sequelae.

Repeated EEGs are normal in the early phase, but shows severe abnormality later in the course of the illness. Mutations in the

---

BOX 6 Classification of West syndrome

Structural/Metabolic
- Pre-, peri- and post-natal cerebral ischemia
- Cerebral malformations
- Neuro-infections sequelae
- *Neurocutaneous syndromes:* Tuberous sclerosis, incontinentia pigmenti
- Hypothalamic hamartoma
- Inborn errors of metabolism: Biotinidase deficiency and other organic acidurias, phenylketonuria, mitochondrial disorders, Menkes disease, nonketotic hyperglycinemia, pyridoxine deficiency

Genetic
- Genetic, e.g., *CDKL-5*, *MeCP 2*, *ARX*, *STXBP-1*, *SPTAN1*, *PLC-β1*
- Chromosomal disorders, e.g., Down syndrome, 1p36 deletion, Pallister-Killian syndrome
- **Unknown**

SCN1A gene encoding the alpha-1 subunit of the sodium channel are detectable in 70–80% of patients with Dravet syndrome.

Seizures are usually refractory. Drugs like carbamazepine, phenytoin and lamotrigine worsen seizures. Sodium valproate, clobazam, and topiramate are the effective AEDs in this syndrome. Stiripentol in conjunction with clobazam or valproate has recently been licensed for use in Dravet syndrome. It is said to control prolonged seizures and status epilepticus better with few patients attaining seizure freedom. Stiripentol is not available in India, but can be procured from other countries (expensive). Early initiation of ketogenic diet has been advocated.

Lennox-Gastaut Syndrome

Lennox-Gastaut syndrome is a severe form of epileptic encephalopathy with onset between 1 year and 8 years of age. It is characterized by *intractable* seizures of different semiologies including tonic, atypical absence, atonic and myoclonic seizures. Two-thirds of patients may have nonconvulsive status epilepticus. The cognitive deterioration or stagnation is common and fluctuates with the seizure frequency. The pathognomonic interictal EEG findings are slow-spike-and-wave discharges (1.5–2.5 Hz) and paroxysmal fast activity.

The etiology of LGS is heterogeneous and similar to epileptic spasms. Valproate and clobazam are the preferred drugs. Levetiracetam, lamotrigine, topiramate, zonisamide and rufinamide are the second line drugs. Steroids and intravenous immunoglobulins may be indicated during periods of increased seizure frequency or status epilepticus. Phenytoin, carbamazepine and intravenous benzodiazepines worsen seizures and may cause tonic status epilepticus in this context. The ketogenic diet is a useful alternative and may be used early in the management. The prognosis is guarded with more than 80% children having persistent epilepsy and severe neurocognitive sequelae.

Epileptic Encephalopathy with CSWS Including LKS

Landau-Kleffner Syndrome

The peak onset is between 5 years and 7 years of age with verbal auditory agnosia in a previously normal child. The language function continues to deteriorate and the course can be gradually progressive or fluctuating. Some children may become mute. Mild behavioral abnormalities are common. Seizures occur in majority (75%) of the children and are infrequent and usually nocturnal. Semiologies may include generalized tonic-clonic, focal motor, atypical absences, head drops and subtle seizures. The EEG is characterized by mainly posterior temporal epileptiform discharges which are markedly activated by sleep.

The main aim of the treatment is to reduce or eliminate the epileptiform discharges. Valproate, benzodiazepines and levetiracetam are the most effective drugs. Poor responders may be treated with ACTH or prednisolone. The role of intravenous immunoglobulins and ketogenic diet is unclear. For medically refractory cases, multiple subpial transection has been used with some success. The seizures and epileptiform abnormalities remit by the age of 15 years. Majority of children are left with permanent language dysfunction. The earlier the onset of LKS, the worse the prognosis with regard to the language function.

Epileptic Encephalopathy with Continuous Spike-and-wave During Sleep

The onset of this epileptic encephalopathy is between 2 months and 12 years of age. The preceding neurodevelopment is normal in 50% children. Seizures are the presenting symptom in 80% children and neuropsychological deterioration in the

rest. The children present with infrequent, nocturnal seizures (simple or complex focal, generalized tonic-clonic or myoclonic seizures). The interictal EEG during wakefulness shows focal or multifocal epileptiform discharges with marked accentuation during sleep.

After 1–2 years, there is increase in seizure frequency with emergence of new seizure types (absence or atonic seizures, negative myoclonus). This is associated with the appearance or deterioration of neurocognitive status. The interictal EEG during wakefulness shows more pronounced abnormalities. During non-rapid eye movement (NREM) sleep, EEG shows continuous or nearly continuous spike-wave discharges (CSWS). This stage is followed by clinico-electroencephalographic remission, usually 2–7 years after the onset. Majority of the children, however, are left with residual moderate to severe neurocognitive deficits.

Early initiation of steroids or ACTH is usually recommended. Intravenous immunoglobulins also have shown promising results. The AEDs, used for LKS, are usually effective. Clobazam once daily dose at night, sometimes in high doses (20–30 mg/day), is said to be effective in anecdotal reports. Limited response has been demonstrated with ketogenic diet.

GENETIC (IDIOPATHIC) GENERALIZED EPILEPSY

Idiopathic epilepsy is a concept that encompasses an otherwise structurally normal brain with epilepsy as the only neurological problem. Genetically determined lowered threshold for generalized seizures is the pathophysiologic basis for this condition. One third of epilepsies in childhood are actually genetic generalized epilepsies (GGE). GGE phenotype is an age-related electroclinical syndrome. GGE patients present with typical absences or GTCS. On detailed historical evaluation the presence of early morning myoclonus in some patients may become apparent. Many patients present with early morning GTCS in the context of sleep deprivation or provoked arousal. Patients with GGE are typically developing children with unremarkable neurologic examination. Neuroimaging is usually normal. EEG background activity is normal and the pathognomonic feature in EEG is the presence of paroxysmal, 3–4 Hz or faster, generalized spike and wave or polyspike-slow wave discharges (regular or irregular depending on the syndrome).

The following syndromes are included under the rubric of GGE:
1. Benign myoclonic epilepsy in infancy
2. Generalized epilepsy with febrile seizures plus (GEFS+)
3. Epilepsy with myoclonic astatic seizures
4. Childhood absence epilepsy
5. Juvenile absence epilepsy (JAE)
6. Juvenile myoclonic epilepsy (JME)
7. Genetic generalized epilepsy with GTCSs only

Childhood Absence Epilepsy

This is an age-related epilepsy syndrome that typically manifests in middle childhood (4–10 years of age). The usual presentation is one of multiple daily *blank spells* in a typically developing child. These episodes are usually noticed by others (parents, siblings, peers and teachers) but the patient himself is not aware. Typical absence seizures manifest as sudden ceasing of activity for few seconds (usually 5–15 s) with associated staring and other automatisms (see typical absence seizure) and prompt resumption of the activity. In untreated or inappropriately or inadequately treated patients with CAE, typical absences can readily be demonstrated by having the child blow a pinwheel (hyperventilation) for 3 min in the outpatient department. This should be attempted in every patient where typical absences are suspected.

The classical EEG abnormality is the generalized 3 Hz spike-wave pattern. Sodium valproate and ethosuximide are the drugs of choice. Most patients are responsive to monotherapy in moderate doses and remain seizure free and outgrow the seizures before 12 years of age.

Juvenile absence epilepsy presents later (7–17 years) with less frequent typical absence seizures. Majority of patients also have GTC seizures in addition to typical absence seizures, sometimes GTCSs precede the absence seizure in onset. The risk of GTCS years after complete remission of absences is known.

Juvenile Myoclonic Epilepsy

Juvenile myoclonic epilepsy presents in adolescence (12–18 years) with GTCS predominantly in the early morning hours, just upon awakening. Usually a cluster of myoclonias herald a GTCS. All patients with JME have myoclonic jerks, 85% have GTCS and 30% have typical absence seizures. EEG shows fast 4–6 Hz irregular generalized polyspike and spike-wave complexes with 30% of patients showing photosensitivity. Seizures are easily controlled on moderate doses sodium valproate monotherapy. Levetiracetam, lamotrigine and topiramate are effective alternatives. Carbamazepine and phenytoin should be should be avoided as they worsen seizures. There is high (80%) recurrence rate of seizures after stopping AED even after many years of seizure control. Most of the patients need lifelong AED treatment.

BENIGN CHILDHOOD FOCAL EPILEPSIES

Benign childhood focal epilepsies are a group of disorders characterized by focal-onset seizures with no underlying structural brain abnormality and presumed functional mechanism for the epilepsy and EEG abnormalities. Their common features include seizures closely related to sleep, no associated neurologic signs, no or mild cognitive impairment, good response to anticonvulsant drugs, spontaneous resolution after few years, normal EEG background with EEG abnormalities greatly enhanced during sleep.

The ILAE task force recognizes three syndromes of benign childhood focal epilepsies:
1. Benign childhood epilepsy with centrotemporal spikes (BCECTS)
2. Early-onset benign childhood occipital epilepsy (Panayiotopoulos type)
3. Late-onset benign childhood occipital epilepsy (Gastaut type).

Benign Childhood Epilepsy with Centrotemporal Spikes

It is also known as Rolandic epilepsy. It is the most common age-related focal epilepsy in childhood with peak frequency of onset between 7 years and 10 years of age. It is characterized by infrequent (25% children have only one seizure) and brief seizures. Majority of the seizures are focal with generalization seen in some children. More than half of the children have seizures during sleep. The cardinal features of rolandic seizures include: *Hemifacial sensorimotor seizures:* tonic face deviation, clonic jerks of cheek or eyelids, numbness; *Oropharyngeal manifestations*: guttural sounds, gargling, hypersalivation; and *Speech arrest*. Rarely, focal motor status epilepticus may occur. There may be associated behavioral or cognitive deficits.

Electroencephalogram shows classical centrotemporal spikes, most pronounced during sleep. Neuroimaging is normal and is *not required* for the classical cases. The prognosis is excellent with remission within few years. However, atypical evolutions are known (< 1%).

Many patients with typical rolandic epilepsy do not need AED treatment, as this is an age-related condition with very infrequent seizures that almost all patients outgrow. There is a subgroup of patients with frequent or prolonged seizures who need treatment.

Sodium valproate, levetiracetam, clobazam are the preferred drugs and carbamazepine and oxcarbazepine may cause worsening of the condition.

Early Onset Benign Childhood Occipital Epilepsy (Panayiotopoulos Type)

Its peak frequency of onset is between 3 years and 6 years of age (range: 1–14 years). It is characterized by infrequent and usually prolonged seizures. Two-thirds of the children have seizures during sleep. The seizures usually begin with variable combination of nausea, retching and vomiting. Other autonomic manifestations like pallor, flushing, cyanosis, coughing or incontinence may be present. These symptoms may proceed to deviation of eyes, unilateral clonic jerks, visual symptoms and loss of consciousness. Status epilepticus and sudden cardiorespiratory arrest are known to occur. EEG shows stereotypic occipital or multifocal spike-wave discharges which are markedly activated by sleep and eye-closed state.

Carbamazepine and valproate are the commonly used drugs. Rarely, aggravation is known to occur with carbamazepine. The prognosis is excellent with majority of children achieving complete seizure remission within few years. Atypical evolutions are extremely rare.

Late Onset Benign Childhood Occipital Epilepsy (Gastaut Type)

The mean age of onset in late onset benign childhood occipital epilepsy is around 8 years (range: 3–15 years). Around 20% patients may have a family history of migraine. Majority of seizures are diurnal. They are frequent but usually brief. The seizures start with visual symptoms, including elementary or formed visual hallucinations, transient amaurosis or visual illusions. They may be followed by hemisensory, motor signs, or unresponsiveness. One-third of patients can have severe postictal, headache, sometimes with nausea or vomiting, closely mimicking migraine. EEG shows occipital paroxysms which are enhanced by sleep and eye-closed state. Children show dramatically good response to carbamazepine. Prognosis is usually good with more than half of the patients achieving remission within 2–4 years of onset.

Other Focal Epilepsies

The most common causes of childhood symptomatic focal epilepsy in our country are perinatal insult, neuroinfection sequelae and calcified granulomas. Mesial temporal lobe epilepsy (MTLE) is another common problem.

Mesial Temporal Lobe Epilepsy

Mesial temporal lobe epilepsy is a specific focal epilepsy syndrome that is commonly refractory to drug treatment. MTLE usually manifests in adolescence with habitual seizures but may present in late childhood. History of complex febrile seizures, febrile status epilepticus or encephalitis like illness in early childhood may be present in 50% of patients. The typical seizures in this syndrome is very stereotypic with visceral aura (epigastric raising sensation) and hypomotor seizures with motionless staring and behavior arrest, oral automatisms (chewing and other repeated lip movements), ipsilateral hand automatisms (fumbling, cloth picking, may appear semi purposeful) with or without head version to contralateral side or dystonic posturing of arms later in the seizures. The seizures very rarely generalize (secondary generalization). Hippocampal sclerosis is the underlying cause in most of the patients but there may be other lesions in mesial temporal lobe such as tumors [ganglioglioma, dysembryoplastic neuroepithelial tumor (DNET)], cortical dysplasia or developmental venous anomaly. Carbamazepine or oxcarbazepine are the usual first line drugs. Some patients are refractory from the beginning but most of the

patients remit for a variable period only to recur later and become drug refractory. Lamotrigine, clobazam, topiramate, lacosamide are effective in some patients who failed on first line drugs. Epilepsy surgery is considered when there is drug resistance. MTLE is one of the most common causes of drug refractory epilepsy in adolescents and young adults. Selective amygdalohippocampectomy with or without anterior temporal lobectomy is a curative surgery with a remission rate of nearly 80%.

IN A NUTSHELL

1. An epileptic seizure can be defined in as a transient occurrence of signs and/or symptoms due to abnormal excessive or synchronous neuronal activity in the brain.
2. Acute symptomatic (or provoked) seizures occur in close temporal association with an acute systemic, metabolic, or toxic insult or in association with an acute CNS insult (infection, stroke, trauma, intracerebral hemorrhage, or acute alcohol intoxication or withdrawal).
3. Etiology and syndromic diagnosis of epilepsies is vital for management and prognosis.
4. Seizures are broadly classified as generalized or focal.
5. Electroencephalogram can only support a clinical diagnosis of epilepsy when it is abnormal but cannot exclude epilepsy when it is normal.
6. In cases of new-onset focal seizures, imaging abnormality can be expected in up to 50% of cases.
7. West syndrome is characterized by epileptic spasms or salaam attacks, hypsarrhythmia/variants on EEG and developmental arrest or regression.
8. Lennox-Gastaut syndrome (LGS) is a severe form of epileptic encephalopathy with onset between 1 years and 8 years of age. It is characterized by intractable seizures of different semiologies including tonic, atypical absence, atonic and myoclonic seizures.
9. Benign childhood focal epilepsies are a group of disorders characterized by focal-onset seizures with no underlying structural brain abnormality and presumed functional mechanism for the epilepsy and EEG abnormalities.
10. The most common causes of childhood symptomatic focal epilepsy in our country are perinatal insult, neuroinfection sequelae and calcified granulomas.

Chapter 42.9
Treatment of Seizures and Epilepsy
Gopinath Musuwadi Subramanian

The management of epilepsy is multidimensional and encompasses several issues centered on the child and the family than a mere act of prescribing medications. The management principles across different types of epilepsies may overlap and share similarities but they should be individualized to a particular child taking into account all relevant factors other than epilepsy.

Bearing the label of epilepsy aside, the immediate and long-term effects of such epilepsy can be far reaching to the child and the family. A single seizure can have disastrous consequences on a child's life at home, school and society. Such events can cause major impact on the family's social, life style and financial aspects and a compulsion to adapt to the new reality. A single event can raise ongoing uncertainty all the way for weeks, months, or years until the diagnosis is entertained or confirmed. Recurrent seizures on the other hand, affect not only the personal and school life of a child or adolescent but also affect the entire family including siblings and close relatives. Uncontrolled epilepsy is another extreme where families find it challenging to balance quality of life with uncertainties from seizures.

The current understanding in pediatric epilepsy has improved the standard of diagnosis, investigations and appropriate treatment. The benefits overflow in improving the awareness and acceptance of such a diagnosis in the society in areas such as learning and employment opportunities. The concept of epilepsy syndrome or named epilepsies helps prognostication in a child or adolescent who fits a particular type. Despite these aspects, there is a wide gap in children with intractable epilepsy where effects are far reaching and difficult to quantify. It is becoming clear that in addition to overt clinical seizures, the impact of subclinical seizures and in select circumstances, recurrent seizures may produce brain damage.

Thus, a compelling case arises from arguments above that every effort should be made in achieving appropriate seizure control and seizure prevention. The first step in the management is arriving at the right diagnosis of epilepsy. It is important to distinguish a seizure from a seizure mimic. Clinical history and witnessed information are invaluable to a diagnosis. It is always vital to consider clinical and diagnostic information complementing each other in confirming the diagnosis of epilepsy. Empirical treatment solely based on investigations alone without clinical correlation should be discouraged as an approach to establish a diagnosis of epilepsy.

The decision to treat recurrence of seizures has to be addressed at two levels. The decision becomes almost imminent in an acute case scenario while such haste should be avoided to give way for a well-thought and a sound judgment for long-term daily treatment. A child presenting with an explosive onset of seizures recurring in clusters over a short period of time or as status epilepticus needs immediate treatment to stabilize and break the vicious pattern of recurring seizures. The goal and outcome is cessation of seizures in the short-term. The question of long-term daily treatment follows after control of seizures in the short-term or when a seizure recurs for the second time or beyond weeks or months after the first event. The decision to daily treatment in the long-term should consider issues well beyond epilepsy.

The management of epilepsy is an ongoing contract between the clinician, the child and the family to ensure appropriate quality of life as prior to diagnosis. The access to medical information, social networking and parent groups are freely available on the internet to parents and caregivers in this digital age. There is another section of the society who carries the social stigma of a diagnosis of epilepsy in their everyday life due to false beliefs and being in a disadvantaged background. They lack awareness that pediatric epilepsy is a treatable diagnosis. It is the duty of the clinician to explore and highlight relevant information to families that may be applicable in a child. In situations, where relevant for e.g., in choosing the right antiepileptic drug (AED) between two or many equally good choices, in making a decision to treat or not to treat in mild or infrequent epilepsies or in agreeing to a decision to wean, it is often helpful in arriving at an informed decision including the views of parents and the child.

GENERAL PRINCIPLES IN PRESCRIBING ANTIEPILEPTIC DRUGS

Decision to Treat or Not to Treat
The decision to treat is based on a firm diagnosis of epilepsy. The first event experienced or witnessed may point to a diagnosis of seizure or the actual type of seizure, focal or generalized and even a named epilepsy syndrome. Such a scenario facilitates early decision to treatment, choosing the right AED and offering prognosis on the seizure outcome. On the other hand, arrival of diagnosis especially of epilepsy syndrome or even the type of seizure is not uncommon to be delayed until very late in the course. Such scenarios can lead to overdiagnosis or misdiagnosis. This can result in unnecessary treatment or even delay in treatment.

The decision to treat is straightforward in epilepsy syndromes such as childhood absence epilepsy (CAE), benign focal epilepsy in childhood and juvenile myoclonic epilepsy (JME), etc. to name a few. The decision to treat should be offered in scenarios where the seizures are characterized by seizure types such as absence seizures, focal or generalized seizures and not necessarily only when an epilepsy syndrome is evident. Infrequently, the decision to treat may arise even after a single unwitnessed seizure based on safety. Events of unwitnessed nature on more than two occasions may mandate a decision to treat without the seizure being characterized adequately. The arguments in above scenarios to treat are valid as long as adequate care has been taken. In circumstances, where a seizure mimic cannot be excluded, it is useful to investigate further than accepting to treat.

The decision not to treat is much more complex and is based on several reasons. It is valid in seizures or epilepsy type where the natural course is predictable with a low recurrence risk and a high chance of remission. The merits and demerits of treatment to influence risk recurrence versus side effects may not favor one to another. These facts are very much true in children with febrile convulsions and benign epilepsy syndromes in the neonatal period, infancy and childhood. It is very common for children not to be treated in the above scenarios. A more complex scenario arises in children with developmental delay where mild seizures occur in the context of intercurrent illnesses. A decision to wait and not treat is acceptable if the implications are discussed with the family.

The decision to *treat* or *not to treat* a patient with a single unprovoked seizure is controversial. Wait and watch policy is appropriate in most of the cases and anticonvulsant drugs may be started after the second episode of seizure. By this approach, 50% of patients who are never going to have the second seizure are not unnecessarily treated with AED for 1–2 years period. Evidence shows that immediate treatment with an anticonvulsant drug reduces the risk of a subsequent seizure in the short-term, but does not alter the long-term outcome.

Treatment of a first unprovoked seizure must also include education and anticipatory guidance to patients and families.

Usual topics discussed are recurrence risk, risks versus benefits of anticonvulsant drug initiation, injury prevention, first aid, school considerations and recreational activities. There is no need for any activity restriction and child should be allowed to be his or her usual self. Helmet use for bicycling, restriction of climbing on heights and supervised swimming is recommended. For those who are found to have photosensitive seizures, we recommend avoidance of provocative lighting as far as possible, patching of one eye (photosensitivity is a binocular phenomenon and the incidence of seizures can be reduced by patching one eye at a time) and wearing glasses with special filters.

Mechanism of Action of Antiepileptic Drugs

Most AED medications have one or more mechanism of actions. A simple basis of understanding AED mechanism of action is their ability to facilitate or inhibit neural transmission at the level of ion channels or neuron receptors. The most important among the ion channels and receptors are sodium and calcium channels, gamma-aminobutyric acid (GABA) and glutamate receptors respectively. A rule of thumb is AEDs with sodium channel blockade are effective against partial seizures while AEDs with calcium channel blockade are effective against absence seizures.

The sodium channel blockade is the most common pathway for several AEDs including phenytoin, carbamazepine, oxcarbamazepine, lamotrigine, valproate, topiramate, rufinamide, lacosamide and zonisamide. The well-known calcium channels of T-type in the thalamic area are blocked by valproate, ethosuximide and zonisamide and hence appropriate medications in absence seizures. GABA activation is best seen with phenobarbitone and benzodiazepines.

Newer and third generation AEDs such as lamotrigine, topiramate and levetiracetam have multiple mechanisms of action. Lamotrigine inhibits voltage gated sodium and calcium channels. Topiramate inhibits sodium channel and glutamate transmission while enhances GABA activation. Levetiracetam inhibits calcium channel and glutamate transmission while enhances GABA activation.

Prescribing the First Antiepileptic Drug

The choice of first AED in majority of instances can be straightforward and specific to the type of epilepsy or epilepsy syndrome. In others, they can become complicated by other factors. These may be factors relevant to an individual patient such as age of the subject, e.g., neonate, child or adolescent, body weight and comorbid diagnosis, factors relevant to medication such as pharmacokinetics, side effects or drug interaction and factors relevant to social issues such as treatment costs to the family.

The choice of first AED in neonatal seizures are narrower than other age groups given that tolerability and safety profile for many of the available agents are unknown in this age. Beyond two years of age, the choice of valproate or carbamazepine for generalized or focal seizures respectively may be the first step. In select situations, the first AED chosen may be one of the new and broad spectrum AED. For example, Lamictal may be chosen in preference to valproate in a child or teenager who is overweight or at risk of gaining weight. Learning and attention difficulties at school may be a factor in deciding against carbamazepine. Ease of introducing and need for rapid escalation of AEDs may narrow choices to those that can be administered by both parenteral and oral routes such as valproate or levetiracetam. The cost of AED also has to be factored keeping the family income in mind to improve compliance and affordability in the long-term with option such as phenobarbitone.

Introducing First Antiepileptic Drug

The rule is starting AEDs on low and slow dose for a new onset diagnosis of epilepsy in non-emergent situations. The commencement is made at the starting dose with increases made every few days or on a weekly basis to titrate to the low maintenance dose range aiming for seizure control. Further increases to maximal doses will be guided by seizure control or emergence of side effects. Monitoring drug levels are often useful to ensure therapeutic levels and confirming medication compliance. Drug levels achieve therapeutic range after a single intravenous administration of loading dose or following five half-lives of oral administration of maintenance doses. A quick therapeutic level is desirable in emergency situations with status epilepticus or multiple clustering of seizures. Systematic measurement of drug levels every 3 or 6 months is not mandatory for all patients. Some practical examples for drug level estimation are in unexplained breakthrough seizures, emergence of side effects, and medication doses being outgrown during growth spurts in an adolescent.

Treatment Failure with First Antiepileptic Drug

Failure to control seizures with the first AED is one of the important determinants to the outcome of epilepsy treatment in the short and long-term. The failure to first AED should be addressed by revisiting history and clinical examination, and ensuring written communication have been understood regarding dose and timing of medication. The failure to control may relate to factors that are easily remediable such as dosing errors, inadequate dosing or choosing the right drug formulation. The failure to first AED after exclusion of remediable factors mandates reviewing of home videos or recording seizures by long-term video-electroencephalography (EEG) recording towards confirmation of seizure or epilepsy syndromes as the distinction between age-related, benign epilepsy syndromes from difficult to control or refractory seizures may emerge at that point.

The failure of first AED to control seizure may manifest at any stage of treatment. Breakthrough seizures may occur after a period of adequate control that may responds to dose titration but further increases may prove unsuccessful. A stepwise approach would be to consider alternative monotherapy in place of the first agent. The second AED agent is titrated up while making no changes to the first AED. Once appropriate seizure control is achieved the first AED may be weaned gradually. It is not uncommon that weaning of first AED may result in seizure relapse indicating that the combination may be necessary. Less frequently, the epilepsy may manifest within the first few days to weeks with such severity that there is a need for alternative monotherapy or combination therapy and early polytherapy becomes necessary. Early polytherapy may be anticipated and discussed with families even at diagnosis in epilepsy syndromes such as Dravet syndrome, Lennox-Gastaut syndrome or Doose syndrome.

Pharmacodynamic interaction A synergistic interaction of valproate and lamotrigine is well known. Valproate levels are reduced by phenobarbital, phenytoin and carbamazepine. The latter three AED levels are increase by valproate. Carbamazepine is an enzyme inducer and reduces levels of phenytoin, valproate and lamotrigine.

Decision to Wean or Stop Antiepileptic Drug

Overall about two-thirds of children with epilepsy will remain seizure free during and after the withdrawal of an AED on completing the minimum treatment period for 2 years or more. The majority of seizure recurrences occur within the first year, during or soon after AED discontinuation.

Among several factors, the specific epilepsy syndrome is often the main determinant to predict the duration of therapy and the risk of seizure recurrence occur after discontinuing the AED than the choice or duration of the AED.

This is best illustrated by AED withdrawal after successful completion of 2 years of treatment in patients with age-dependent syndromes given the low risk of recurrence with benign epilepsy in infancy and childhood. On the other hand, AED withdrawal should be deferred for several years or even indefinitely in symptomatic epilepsy or some patients with JME.

Seizure and EEG remission is also an important determinant for AED withdrawal in children with epilepsy as both these factors are desirable outcomes to be attained after the required period of treatment and may predict low risk of recurrence.

Antiepileptic drug withdrawal can be uncertain and may be considered high risk in children with epilepsy whose seizure control was late and difficult to achieve only after institution of alternative monotherapy or polytherapy. In such circumstances, drug withdrawal may prove to be inadequate in children with well controlled seizures leading to seizure relapse. Treatment resumption after a seizure relapse is likely to restore the previous seizure control in the majority but failure to achieve previous seizure control in some can become a major issue. The uncertainty that another AED may or may not work should be explored and the benefit versus risk of drug withdrawal needs to be discussed with the family.

Refractory Epilepsy

Refractory seizures in children are challenging in diagnosis and management. The use of phrase *refractory epilepsy* is very often used interchangeably with intractable epilepsy. The most simple and practical definition for refractory epilepsy is failure of two AED treatment at maximum tolerated doses with least side effects for a period of 2 years and a referral to a specialist epilepsy center encouraged. It is not unusual that such a diagnosis is arrived earlier in the initial few months and referral to a specialist center is encouraged for further evaluation. The available prediction models in children with refractory seizures are few and inadequate. This is exemplified by the fact that children who turn out with a poor epilepsy outcome do not begin so at start of epilepsy. On the other hand, children with epilepsy who started with poor control later achieve better control.

ANTIEPILEPTIC DRUGS

The starting and maintenance doses along with the non-serious, common and serious side effects are summarized in the **Table 1**. The updated ILAE evidence review of AED efficacy and effectiveness as initial monotherapy for epileptic seizures and

Table 1 Dosages and side effects of antiepileptic drugs

Antiepileptic drug	Starting dose (mg/kg/day)	Maintenance dose (mg/kg/day)	Number of doses	Nonserious side effects	Serious side effects
Carbamazepine*	4	20–30	2–3	Somnolence, weight gain, hyponatremia, transient leukopenia	SJS, agranulocytosis, aplastic anemia, liver toxicity
Clobazam#	0.25–1.00	0.5–1.0	1–3	Somnolence	Tolerance
Clonazepam#	0.05	0.1–0.2	2–3	Somnolence	Tolerance
Ethosuximide	10	20–30	1–2	Abdominal pain, anorexia	SJS
Phenobarbitone	3	3–5	1–2	Somnolence	SJS
Phenytoin	5	4–10	2	Gingival hyperplasia, coarsening of facies, hirsuitism	SJS
Nitrazepam#	0.10–0.25	0.5–1.0	2	Somnolence	Tolerance; drooling and aspiration
Sodium valproate	10	15–40	2–3	Weight gain, tremor, alopecia	Liver toxicity, SJS
Second and third-generation antiepileptic drugs					
Lamotrigine#	0.5	2–10	2	Somnolence, dizziness	SJS
Lamotrigine with Valproate	0.15	1–5	2	Somnolence, dizziness	SJS
Lamotrigine with enzyme inducers	0.5	5–15	2	Somnolence, dizziness	SJS
Levetiracetam#	5	20–60	2	Somnolence, dizziness	Behavioral issues
Oxcarbamazepine*	5	20–40	2–3	Somnolence, dizziness, hyponatremia	SJS
Topiramate#	0.5–1	2–10	2	Weight loss, hypohidrosis, fever, crystalluria and renal stones	Cognitive dysfunction, word finding difficulty
Vigabatrin* in infantile spasms	50	150	2	Hyperactivity	Visual field defects, retinopathy
Sulthiame	5	5–15	2–3	Paresthesia, insomnolence, anorexia	SJS
Felbamate	15	30–45	2	Vomiting, dizziness, hyperactivity	SJS, agranulocytosis, aplastic anemia, liver toxicity
Gabapentin	5–10	20–60	2–3	Aggression, hyperactivity	
Zonisamide	2	8–12	2	Hypohidrosis, fever, crystalluria	
Stiripentol* in Dravet syndrome	25	50	2–3	Somnolence, weight loss, abdominal pain	
Rufinamide* in LGS	10	30–40	2	Somnolence, vomiting	

* Usually commencing starting dose and increase by the same dose amount every 2–3 days to lower maintenance dose range.

Abbreviation: SJS, Stevens–Johnson syndrome.

syndromes in the pediatric age group published in January 2013 summarizes the current position of available agents. The ILAE evidence is compared against recommendations from expert review and guidelines from various bodies in **Table 2**. The updated evidence provides data relevant for children in three seizure types and two epilepsy syndromes. The three seizure types are children with partial-onset seizures, children with generalized onset tonic-clonic seizures and children with absence seizures. The epilepsy syndromes are the benign childhood epilepsy with centrotemporal spikes (BCECT) and JME.

The updated evidence was concluded on data from 64 randomized controlled trials (RCTs) over the last 72 years and 11 meta-analyses. The latest recommendation and treatment evidence available on children with absence seizures mirror existing or standard practice of treatment in this group of children. The recommendation falls short in choosing the ideal agent with established efficacy or effectiveness in children with partial and generalized seizures and the children with epilepsy syndromes namely the BCECTs and JME. However, the study data identifies the availability of several agents for daily practice. It ultimately rests on the individual physician to use them to the best of their experience. Syndrome-based treatment of epilepsy and epilepsy syndromes is already discussed in the previous chapter.

NONPHARMACOLOGICAL THERAPIES

Epilepsy Surgery
Candidacy for epilepsy surgery requires a diagnosis of refractory epilepsy and identification of a surgical substrate that when resected leads to improved seizure control and even complete seizure freedom. Certain etiologies such as focal cortical dysplasia, focal hamartoma in tuberous sclerosis, hypothalamic hamartoma, focal area of gliosis and hemispheric syndromes such as Rasmussen encephalitis and hemimegalencephaly have a high chance of being identified with a surgical substrate for resection than intractable epilepsy from genetic, metabolic and degenerative conditions. Focal cortical resection or lesionectomy, hemispherectomy and corpus callosotomy are some of the commonly performed surgeries.

Ketogenic Diet
The Ketogenic diet (KD) is a dietary treatment altering the ratio of fat to nonfat food in increasing ratios from 1:1 to 4:1 with the aim of maximizing ketone production in a way that improves seizure control. It is effective in all seizure types, generalized and partial and a trial of 3–6 months is considered adequate to assess efficacy. It is indicated as one of the treatment options very early in Doose syndrome and in refractory seizures related to Dravet syndrome, Rett syndrome, migration disorders and tuberous sclerosis complex. The diet is carefully prepared by an experienced dietician supervised by the neurologist. This involves a highly motivated child and family who can perform daily ketone assessment in the urine and blood. The side effects are reduced palatability, weight loss, dehydration and nutrient deficiency in the short-term and risk of kidney stones and fatty liver in the long-term. In responders with KD, a 50% seizure reduction in 33% and complete seizure control in 15% is achievable in children who have refractory seizures.

Vagal Nerve Stimulation

Vagal nerve stimulation is a treatment in refractory epilepsy those who are not amenable to surgery. With its minimal adverse side effects (hoarse voice, throat pain, cough and headache), lack of pharmacokinetic interactions with drug therapies, negligible compliance issues and improvement in quality of life, the VNS therapy is useful in one third to one half of children in reducing the severity and frequency of seizures in short-term studies.

PROGNOSIS

Seventy percent of children with epilepsy, who are seizure-free for 1–2 years on anticonvulsants, can successfully stop their medications. Specific epilepsy syndrome diagnosis may be helpful in predicting the success or failure of discontinuing anticonvulsant treatment. Around 15% of childhood epilepsy syndromes (e.g., benign rolandic epilepsy, Panayiotopoulos syndrome) always remit. 10% of syndromes (e.g., Ohtahara syndrome, Dravet syndrome, Lennox-Gastaut syndrome, JME, reading epilepsy) usually never remit. For the rest 75% of childhood epilepsy syndromes, the prognosis is intermediate—some patients remit and some do not.

Children with epilepsy are at five times higher risk of dying as compared to the general population. The causes may include direct complication of seizure (e.g., aspiration, arrhythmia), accident, co-morbidities, suicide or sudden unexpected death in epilepsy (SUDEP). SUDEP is rare in children with epilepsy. The adult studies have identified many risk factors for SUDEP and include high seizure frequency especially generalized tonic-clonic seizures, polytherapy, early onset of epilepsy (< 15 years) and associated intellectual disability.

Raspall-Chaure M, Neville BG, Scott RC. The medical management of the epilepsies in children: conceptual and practical considerations. Lancet Neurol. 2008;7:57-69.

IN A NUTSHELL

1. Presumption of a seizure diagnosis without considering mimics in a paroxysmal event with loss of consciousness can lead to over diagnosis of seizures.
2. The frequency, intensity and duration of individual seizures in an untreated epilepsy almost always progresses or evolves with time making it unlikely for a diagnosis of epilepsy to be overlooked over months or years.
3. Focal onset of a seizure in unwitnessed or partially witnessed seizures can be easily overlooked. Careful history, home videos and documenting seizures during video electro-encephalography (EEG) recording should be considered during evaluation.
4. Valproate is a safe first antiepileptic drug (AED) choice in children with afebrile seizures over 2 years of age. It is also a useful choice when partial seizures cannot be distinguished from absence seizures in young children.
5. Empirical trial of AED treatment for 3–6 months should not be used as a short cut approach to diagnose epilepsy.
6. Routine and monthly blood test for drug levels, progress EEG's are to be avoided unless the investigations are meant to recommend a change in management.
7. The balance of improved seizure control by frequent and aggressive drug titration should be weighed against exacerbation of dose related side effects. The drug effectiveness in a given patient should be considered individually than drug efficacy.
8. The evidence based management can be used as a framework in the treatment of pediatric epilepsy but should be individualized to a patient by the clinician considering the seizure type or epilepsy syndrome, age, comorbidity and the social circumstances.

Chapter 42.10
Febrile Seizures
Sangeetha Yoganathan

Febrile seizure is a seizure accompanied by fever, without CNS infection, that occurs in infants and children between 6 months and 60 months of age and the documented temperature during febrile seizures should be at least 37.8°C. It occurs in 2–14% of all children worldwide and is also the most common convulsive event in children younger than 60 months. Data from United States found an incidence of one-half million febrile seizure events occurring per year. Peak incidence has been reported around 18 months of age. Reported incidence of febrile seizures from a home based survey in a South Indian state was up to 10%. In children undergoing surgery for drug resistant temporal lobe epilepsy, nearly three fourths have a history of febrile seizures in childhood.

ETIOLOGY

Febrile seizures can occur with febrile events following bacterial or viral infections. Most common cause of fever in children is viral and the febrile seizures were more commonly reported in children with infection due to human herpesvirus 6 (HHV-6), influenza, parainfluenza, adenovirus, respiratory syncytial virus and rotavirus infection. Febrile seizures were also documented to occur following vaccination with diphtheria, pertussis, tetanus (DPT) and measles, mumps, rubella (MMR) vaccines.

PATHOPHYSIOLOGY

Febrile seizures do not occur in all children with fever and the exact pathophysiology is not clear. Various possible postulates were put forward to explain the mechanism of febrile seizures which are briefly discussed here:

Rise in temperature Magnitude of the fever does not seem to affect the occurrence of febrile seizures. Some children have febrile seizures with low temperature and these children are at an increased risk of having recurrences due to lower seizure threshold. Hyperthermia can decrease gamma aminobutyric acid A (GABA-A) receptor-mediated inhibition and hence shift the balance towards excitation. This appears to be mediated by reducing GABA release from presynaptic terminals, but hyperthermia may also decrease postsynaptic GABA receptor function. Various other transmitters and modulators including neuropeptide Y antagonist, arginine and vasopressin have also been studied in experimental models.

Inflammatory mediators Tumor necrosis factor α (TNF-α), interleukin (IL)-1α, IL-1β, and IL-6 are the proinflammatory cytokines. IL-1β acts by increasing the release of glutamate from glia and neurons and by decreasing GABA-A receptor-mediated currents. As a result, there is increased excitation and decreased inhibition. There is an increased frequency of allele promoting IL-1β production and also increased levels of IL-1β in cerebrospinal fluid (CSF) in children with febrile seizures.

Genetic factors Genetics of febrile seizures is complex and is continually expanding. It may explain the high risk of febrile seizures in certain families than others. Positive family history was identified in 25–40% of children with febrile seizures. Chromosomes with reported linkages for febrile seizures are 2q, 5q, 5, 8q, 19p, 19q and also are the genes related to neuronal sodium channel receptor.

Hyperventilation-alkalosis In children with fever there is an increase in respiratory rate which could lead to respiratory alkalosis resulting in increased neuronal excitability. The role of this mechanism in the generation of febrile seizures in children is unclear.

Double hit hypothesis Cortical malformations such as focal cortical dysplasias and microdysgenesis can lower the seizure threshold in a child with febrile seizures and can lead to prolonged status epilepticus. On the other hand, a strong association exists between prolonged and focal febrile seizures and subsequent development of temporal lobe epilepsy.

CLINICAL DIAGNOSIS

Diagnosis of febrile seizures is essentially clinical. There are two types of febrile seizures namely simple and complex febrile seizures.
1. *Simple febrile seizures* are defined as primary generalized seizures occurring in association with fever, lasting for less than 15 min and do not recur within 24 hours.
2. *Complex febrile seizures* are defined as focal, prolonged (more than 15 min), and/or recurrence within 24 hours.

History taking and careful clinical examination is needed to exclude meningitis. History with regard to seizure includes detailed elicitation of semiology, duration, frequency and family history of febrile seizures or epilepsy. Focused clinical examination to look for meningeal signs, signs of raised intracranial pressure and focal neurological deficit is mandatory.

Febrile status epilepticus refers to seizures associated with fever and lasting for more than 30 min. It occurs in 5% of all children with febrile seizures and accounts for 25% of children with status epilepticus. The seizures in febrile status epilepticus is usually convulsive and may be generalized or partial onset with secondary generalization. Studies have shown that febrile status epilepticus is more likely to occur in children with family history of epilepsy and in children with premorbid neurological insult.

A multicentric FEBSTAT study prospectively enrolled 199 children with febrile status epilepticus and analyzed the data on the emergency management of febrile status epilepticus. Data analysis found that children with febrile status epilepticus require an early administration of antiepileptic drugs for control of seizures and even with treatment the seizures might persist for a significant period of time. This study concluded that a standard protocol for the prehospital management of febrile status epilepticus is essential as earlier onset of treatment results in better outcome.

Complex Febrile Seizures and Mesial Temporal Sclerosis
Complex febrile seizures and febrile status epilepticus are associated with subsequent development of mesial temporal lobe epilepsy. Various studies have shown that 30% of patients with mesial temporal sclerosis had a history of febrile status epilepticus. One prevailing hypotheses is that febrile status epilepticus can lead to acute hippocampal injury and later lead on to mesial temporal sclerosis. Other hypotheses states that febrile seizures, febrile status epilepticus and mesial temporal epilepsy are different presentations of an injured hippocampus or genetically predisposed.

Retrospective studies from epilepsy centers have found that adults with refractory temporal lobe epilepsy had a history of complex febrile seizures or febrile status epilepticus in childhood. However, population based studies have not confirmed this association. Published data had shown that magnetic resonance imaging performed within 72 hours of febrile status epilepticus has a good predictive ability of later occurrence of mesial temporal sclerosis. Genetic predisposition, febrile seizures after infection with HHV-6 and HHV-7, pre-existing malformation such as focal cortical dysplasia have also been implicated in the development

of mesial temporal sclerosis. Ongoing multicentric prospective studies might solve the existing controversy regarding the association of febrile seizures and mesial temporal sclerosis.

DIFFERENTIAL DIAGNOSIS

In any infant with fever and seizures, the possibilities that are to be considered are febrile seizures and acute pyogenic meningitis. Large retrospective surveys of outcome in children with fever and seizures found that the diagnosis of meningitis in children with febrile seizures varied from 1% to 7%. In children having both fever provoked seizures and unprovoked seizures with a positive family history of epilepsy, consider the possibility of generalized epilepsy with febrile seizures plus (GEFS+). In a normally developing child with infantile onset febrile seizures followed by intractable epilepsy and disturbed psychomotor development, should raise the suspect for Dravet syndrome, an epileptic encephalopathy. Dravet syndrome and GEFS+ are channelopathies with known mutations in the neuronal sodium channel 1A (SCN1A). Children having focal seizures or prolonged febrile seizures, one should screen for an underlying structural pathology like mesial temporal sclerosis or focal cortical dysplasias. L-2 hydroxyglutaric aciduria is a neurometabolic syndrome with frequent febrile seizures as an initial presenting symptom and can later progress to have myoclonus, pyramidal, extrapyramidal and cerebellar signs.

APPROACH TO A CHILD WITH FEBRILE SEIZURES

History taking and meticulous clinical examination is required in all children with febrile seizures. Diagnostic testing is not warranted in most of the cases.

Search for fever etiology Pediatricians should plan investigations in children with febrile convulsions to identify the cause for fever. Complete blood count is done as a part of fever evaluation rather than as a part of routine investigation.

Routine investigations American Academy of Pediatrics (AAP) Subcommittee strongly recommends that testing of routine blood parameters like serum electrolytes, calcium, phosphorus, magnesium, blood glucose or complete blood cell count is not essential in children with febrile seizures.

Role of lumbar puncture Evidence from observational studies recommends that lumbar puncture should be done in any child with fever, seizures and meningeal signs (e.g., neck stiffness, Kernig and/or Brudzinski sign). Lumbar puncture is optional in children aged between 6 months and 12 months with febrile seizures if the child had not received *Haemophilus influenzae* type b (Hib) or *Streptococcus pneumoniae* vaccines, immunization status cannot be determined with an increased risk of bacterial meningitis or pretreated with antibiotics.

Electroencephalography An electroencephalography (EEG) should not be performed in a neurologically healthy child with simple febrile seizures, as it is not only expensive but also increases the parental anxiety. Cochrane review on the utility of EEG in children with complex febrile seizures concluded that there is no evidence to support or refute the use and timing of EEG in these children.

Neuroimaging Neuroimaging should not be performed in the routine evaluation of the child with a simple febrile seizure. Neuroimaging should be done in all children with febrile status epilepticus, neurological examination revealing focal neurological deficit and signs of raised intracranial tension. Magnetic resonance imaging of brain with an epilepsy protocol is essential in children with history of febrile seizures and refractory epilepsy to rule out focal cortical dysplasia and mesial temporal sclerosis.

MANAGEMENT

Antipyretics

Antipyretic agents act by the alteration of prostaglandin synthesis. Elevated levels of prostaglandins E2 and F2α in the CSF have been found to be associated with febrile seizures. Ibuprofen is an inhibitor of cyclooxygenase-1 (COX-1) than COX-2 whereas diclofenac is an inhibitor of both these enzymes. Acetaminophen acts by reducing the prostaglandins E in the central nervous system. Randomized controlled trials have found that the use of antipyretic agents in children with previous febrile seizures were ineffective in the prevention of recurrent febrile seizures. Paracetamol may provide comfort and symptomatic relief, but should not be recommended to prevent further febrile convulsions. Tepid sponging during febrile episodes had been found to be ineffective in preventing the recurrence of febrile seizures.

Acute Management

Airway maintenance, breathing and circulation must be the priority in any child with febrile seizures. Benzodiazepines are used in the acute management of children with febrile seizures. Diazepam (rectal, intravenous), lorazepam (intravenous, intranasal), midazolam (intramuscular, intranasal, intravenous, buccal) have been found to be safe and effective in the control of prolonged febrile seizures in children. Dosages of these drugs are mentioned in the **Table 1**.

Management of Febrile Seizures in Hospital Setting

In most of the cases, febrile convulsions stop spontaneously and in case of failure of seizures to cease spontaneously, maintenance of airway, breathing and circulation are the priorities. Intravenous access should be established and first dose of benzodiazepine is administered. Consider repeating the dose of benzodiazepine if seizures are not controlled. Febrile status epilepticus should be treated as per standard protocol for management of status epilepticus.

Management of Febrile Seizures in Home Setting

During the active seizure episodes, parents should be instructed to remain calm and avoid panic. They should make an observation of the semiology and duration of seizures. Child's clothing should be loosened and the child should be placed in the lateral decubitus position to avoid aspiration of saliva or vomitus. No attempts should be made to administer any drugs or fluids orally. Parents can administer rectal diazepam or intranasal midazolam in case of prolonged seizure lasting over 2–3 min.

Prophylaxis Therapy

Intermittent Prophylaxis

Rapidly acting anticonvulsants are used during the fever episodes in attempt to reduce the risk of recurrent febrile seizures.

Table 1 List of drugs used in acute management of prolonged febrile seizures

Drug	Route of delivery	Dosage
Midazolam	Intravenous	0.2 mg/kg/dose
	Buccal	0.2–0.5 mg/kg/dose
	Intranasal	0.2 mg/kg/dose
	Intramuscular	0.2 mg/kg/dose
Diazepam	Intravenous	0.3 mg/kg/dose
	Rectal	0.5 mg/kg/dose
Lorazepam	Intravenous	0.1 mg/kg/dose
	Intranasal	0.1 mg/kg/dose

Intermittent prophylaxis should be considered only if there are frequent seizures in a short period (3 or more in 6 months; 4 or more in a year) or if the seizures are prolonged for more than 15 min or requiring pharmacological therapy for control. Studies have shown that intermittent clobazam therapy and diazepam prophylaxis had similar efficacy but adverse effects including drowsiness and sedation were lower in children receiving clobazam. The dosage of oral diazepam is 0.3 mg/kg/dose every 8 hourly and the dosage of oral clobazam is 1 mg/kg/day in 2 divided doses for first 48 hours after the onset of fever. There is no evidence for therapies to prevent subsequent epilepsy and to support the prophylaxis for preventing recurrences of simple febrile seizures.

Continuous Prophylaxis

There is evidence that continuous therapy with antiepileptic medications would reduce the risk of recurrences. Sodium valproate is the preferred antiepileptic drug in children with a need for continuous prophylaxis. Phenobarbitone is less preferred nowadays due to the high prevalence of adverse effects on cognition and behavior in these children.

RISK OF RECURRENCE

After the first episode of febrile seizures, 30% of children had one recurrence; 15% had second recurrences and 7% had three or more recurrences. The risk of recurrence was high during 12–24 months of age. Risk factors predicting the recurrence of simple and complex febrile seizures are listed here:

- Early age of onset (< 15 months)
- Epilepsy in first-degree relatives
- Febrile seizures in first-degree relatives
- Frequent febrile illness
- Low temperature at the onset of the febrile seizure.

Children with neurodevelopmental disabilities, family history of epilepsy and complex febrile seizures are at an increased risk of recurrence for unprovoked seizures. The general risk of febrile seizure recurrence is estimated at around 30–40% and the frequency of recurrence is 10% if there are no risk factors, 25–50% if there are 1–2 risk factors and 50–100% if there are 3 or more risk factors. Risk of epilepsy in patients with simple febrile seizures is 1–1.5%. Risk of epilepsy in patients with complex febrile seizures is between 4% and 15%.

EDUCATION TO FAMILIES

The quality of life in parents of children with febrile seizures can be impaired due to fear of recurrences, fear of subsequent epilepsy, apprehension and anxiety during each febrile episodes. Most important step in the management is the counseling of family with children having febrile seizures. Pediatricians must consider the following steps while counseling the family:

- Describe in as much detail as possible the features of febrile seizures and the benign nature of illness.

- Instruct on the need of appropriateness of anticonvulsive therapy, their risks and benefits.
- Verify that the instructions for fever control and domiciliary management of seizures are well understood.

LONG-TERM OUTCOME

Febrile seizures are benign disorders with an excellent outcome and population based studies have shown normal intellect and behavior, even for complex febrile seizures. There is no data showing increased risk for mortality and morbidity in children with simple febrile seizures.

IN A NUTSHELL

1. Febrile seizures are the most common convulsive event in children between 6 months and 60 months.
2. Majority are simple febrile seizures.
3. Diagnosis is essentially clinical.
4. Long-term continuous antiepileptic drugs are not recommended in children with simple febrile seizures.
5. Intermittent prophylaxis must be used in selected cases.
6. Long-term outcome in these children is excellent.
7. Education of caregivers is crucial in the management of febrile seizures.

Chapter 42.11
Status Epilepticus
Ravindra Arya, Katrina Peariso

Status epilepticus (SE) is a common neurological emergency in pediatric practice. This chapter presents an overview of convulsive status epilepticus (CSE) in children older than the neonatal age group and discusses its definition, epidemiology, management and outcomes with special reference to practice in resource poor countries (RPCs). RPCs are countries classified by the World Bank as belonging to low and middle income groups, and encompass those situated in tropical and subtropical regions. The chapter is focused on early and established SE and refractory SE is reviewed only briefly. The pathophysiology of SE, mechanisms of refractoriness, nonconvulsive SE and details of continuous electroencephalography (EEG) monitoring are not discussed further.

DEFINITION

Status epilepticus can be defined at several levels. Mechanistically, it represents failure of intrinsic homeostatic mechanisms to terminate a seizure after onset, such that it would not resolve without extraneous intervention. From a physiological perspective it represents duration of a seizure sufficient by itself to compromise neuronal survival. Historically, SE has been recognized to be a state without inter-ictal recovery of consciousness to baseline level. This heuristic is reflected in the 1964 definition by the first International League Against Epilepsy (ILAE) classification of epileptic seizures, where SE was defined as a condition when "seizures persist for a sufficient length of time or are repeated frequently enough to produce a fixed and enduring condition". In the 1981 revision also, the lack of inter-ictal recovery formed the basis of the definition of SE: "seizure persists for a sufficient length of time or is repeated frequently enough that recovery between attacks does not occur". From an operational standpoint, the need for specifying such duration criteria for a seizure or a cluster of seizures without recovery of consciousness to baseline was long recognized. Biologically such duration should probably reflect compromised neuronal survival in an otherwise normally perfused and oxygenated brain. Experiments in primates showed that seizures lasting 82–299 min can lead to ischemic cellular changes in certain regions of the brain including hippocampus. Specifically, it was observed that circumscribed damage in the CA1 region of hippocampus could be seen with seizures lasting more than 30 minutes.

Culminating physiological and indirect clinical evidence led Epilepsy Foundation of America's working group to define SE as *more than 30 min of continuous seizure activity, or, more than or equal to two sequential seizures without full recovery of consciousness between seizures*. In the evolution of continued seizure activity, a period of around 30 min seemed to represent a physiological watershed, where systemic complications began to surface and the metabolism switched from aerobic to anaerobic. However, physicians were justifiably hesitant to wait for 30 min before treating the patient with parenteral antiseizure medications. Clinical observational studies in diverse populations supported this view since most of the seizures were found to last less than or equal to 5 min. Hence, a downward revision of the critical duration to define SE began, leading to the current definition where a generalized convulsive SE in adults and children more than or equal to 5 years of age is defined as more than or equal to 5 min of continuous seizures or more than or equal to two discrete seizures without complete recovery of consciousness in between. A concept of serial seizures was introduced for a cluster of discrete seizures with interictal recovery of consciousness to baseline level. Further,

it was recognized that for a majority of seizures occurring in the out-of-hospital settings, it is virtually impossible to ascertain the onset and hence to determine even the approximate duration. Hence the definition of SE was expanded to include any patient who is brought convulsing to the emergency room **(Box 1)**.

As a seizure prolongs beyond 5 min, additional terms are used to describe the phases of evolving SE: early (5–30 min), established (30–60 min), and refractory SE (≥ 60 min). Children younger than 5 years represent a special population where physiological data to inform a duration cut-off are lacking, and the onset of seizure may not be well recognized. Perhaps a longer time frame of 10–15 min can be allowed for the definition, particularly in febrile SE which represents an important subset of this group. The issue of asertaination of seizure onset is further relevant to RPCs and alternative definitions have been proposed, though not well accepted. At present, we believe that the operational cut-off of 5 min or presentation to the emergency facility in active convulsions can be used as criteria for treatment decisions, even in younger children beyond early infancy.

EPIDEMIOLOGY

Worldwide, the incidence of SE shows a bimodal distribution with peaks in infancy and the elderly. A systematic review found the highest incidence of 135–156 episodes/100,000 persons/year in children less than or equal to 1 year of age. Overall, the incidence of SE was found to vary from 3.9 to 38 episodes/10,000 persons/year in children, depending on the inclusion criteria of the individual studies. Particularly, the lower figure was seen in a study limited to generalized CSE. The incidence is expected to be higher in RPCs. A hospital-based cohort study from Africa found that the incidence of confirmed CSE was 35 (95% CI 27–46) per 100,000 children/year overall, and was 52 (21–107) and 85 (62–114) per 100,000/year in children aged 1–11 months and 12–59 months, respectively. Although there is a lack of similar prospective population-based pediatric data from South-East Asia, a retrospective study from India found that SE constituted 6.7% of children admitted to the intensive care unit in a tertiary care center.

CAUSES AND RISK FACTORS

Status epilepticus can be a first manifestation of any disease process leading to acute convulsive seizures or can occur in patients known to have epilepsy. In the pediatric population, prolonged febrile seizures constitute the most common subgroup and account for up to 35% of all episodes of SE. From 16% to 38% of SE episodes have been noted to occur in children with a prior diagnosis of epilepsy, with low antiepileptic drug (AED) levels being the most common risk factor. In developing countries, the causes for SE are different with locally prevalent neurological and systemic infections being significant contributors. In a study from sub-Saharan Africa, 58% of episodes with confirmed CSE were attributable to malaria or malaria-associated febrile seizures. Studies from India have noted acute bacterial meningitis and viral encephalitis to be common underlying etiologies. In a randomized controlled trial (RCT) from India comparing 2 routes of administration of lorazepam, 49% of the episodes of acute convulsive seizures presenting to the emergency room were attributable to neurocysticercosis.

Overall, any pathology which can trigger an acute symptomatic seizure can cause a CSE. This includes neurological and systemic

---

BOX 1 **Current operational definition of convulsive status epilepticus in adults and children ≥ 5 years of age**

1. Continuous seizure lasting ≥ 5 min
2. Two or more seizures without inter-ictal recovery to consciousness to baseline level
3. Patient brought convulsing to the emergency health-care facility.

infections, acute vascular events, traumatic brain injury, and immune, metabolic or toxic encephalopathies. Similarly, epilepsies of any etiology can either have SE as their first presentation, or can experience an exacerbation and present as SE. The specific risk factors leading to such an exacerbation are diverse and include decreased levels of maintenance AEDs (caused in turn by lack of adherence, scheduled withdrawal, insufficient dose, interaction with concurrent medications, growth spurt, etc.), intercurrent illness, exposure to a known trigger (e.g., sleep deprivation in case of certain idiopathic generalized epilepsy syndromes), or metabolic decompensation.

Febrile Status Epilepticus

One of most common subgroups of childhood SE, febrile status epilepticus (FSE) is defined as a prolonged febrile seizure that continues for more than or equal to 30 min. FSE accounts for approximately 25% of all pediatric SE cases and over 66% of cases in children less than or equal to 2 years of age in the United States and Europe. In developing countries, FSE is second only to neurological infections as an underlying cause for SE. However, it is sometimes virtually impossible to distinguish an acute symptomatic SE from FSE in a child with neurological infection. While the mortality rates associated with FSE have been negligible, the morbidity associated with the respiratory and hemodynamic compromise is not. In addition, there is a higher rate of developmental delays and subsequent epilepsy amongst patients with prolonged febrile seizures, suggesting potential additional long-term morbidity. In the recent FEBSTAT study, about 10% of children with a single episode of FSE were noted to have changes on brain magnetic resonance imaging (MRI) in the hippocampal region. Follow-up imaging performed on patients with initial MRI changes 1 year after their FSE found that about 86% of them demonstrated hippocampal volume loss and about 71% had obvious hippocampal sclerosis. As hippocampal sclerosis is a frequent substrate in patients with temporal lobe epilepsy (TLE), these results offer supportive evidence linking FSE to the development of TLE.

Another valuable insight into FSE gained from the FEBSTAT study is the direct correlation between the time to initial treatment with benzodiazepines and the overall duration of the seizure. The FEBSTAT study showed that 90% (179/199) of children with FSE required at least 1 medication, and 78% required 2 medications to abort their seizures. In this study, where the median seizure length was 68 min, for every 2.7 min delay in the initial treatment, there was an associated 1.3 min increase in seizure duration. This finding is indirectly supported by another study which noted significantly shorter median seizure times than those seen in the FEBSTAT study (35 min versus 68 min) which were attributed to comparatively shorter emergency medical services (EMS) arrival times, and more children receiving their first medication from EMS in the prehospital setting in Israel than in the United States (55% vs 41%). Both of these studies concluded that more education regarding recognition of ongoing SE and aggressive treatment of FSE in the prehospital and emergency room setting will improve the outcomes for these children. In settings where prehospital care is not readily available or the EMS providers are unable to administer benzodiazepines, early treatment is more challenging. Educating the families of children with febrile seizures regarding when to seek medical attention and providing them with a dose of rescue medication that may be administered, if a seizure lasts longer than 5 min can still make a difference, as 10% of children with febrile seizures are likely to have FSE.

MANAGEMENT

Objectives of Treatment

There are several targets that have to be simultaneously addressed to optimize the outcome of a child with CSE. These include:

support of critical physiological functions (airway, breathing and circulation) to ensure adequate brain oxygenation and perfusion, termination of clinical and electrical ictal activity, identification and management of precipitating factors, and prevention and treatment of systemic complications of SE. In a subgroup of patients with CSE, it is also pertinent to attempt identification and proximate management of the underlying disease process.

Initial Stabilization

This phase of management of a child with CSE is quite similar to that in any other medical emergency, and is better covered in the intensive care literature. The initial goal is to optimize respiratory and hemodynamic function to ensure adequate oxygenation, perfusion and nutrition (glucose levels) of the brain. One of the first targets is to establish a patent airway which can be challenging in an actively convulsing child. Increased tone of mandibular muscles leading to a tightly clenched jaw, obstruction by a swollen or bitten tongue, or extraneous circumstantial factors in some patients can be potential barriers to a successful airway. Proper positioning of the head, oral and nasopharyngeal suction of the secretions, a nasopharyngeal airway and oxygen supplementation via a non-rebreathing mask are the immediate first steps. At this stage, a rapid assessment regarding need for assisted ventilation should be made. The SE itself, the underlying pathology or ongoing drug therapy can cause abnormal and ineffective breathing patterns that should be recognized. Although bag and mask ventilation can be appropriate as a temporizing measure, a rapid sequence intubation is recommended for children with anticipated need for prolonged ventilation, hemodynamic compromise or features suggestive of increased intracranial pressure (ICP). The next step after stabilizing respiration is to obtain good quality vascular access to administer fluids, electrolytes and medications. At least two large bore intravenous (IV) catheters should be promptly established, which can be challenging in an acutely convulsing child because of movements or collapsed veins. Several different nonvenous routes have been tried for the treatment of acute convulsive seizures and SE, which are summarized below. In children less than or equal to 6 years of age, the intraosseous route is another option.

Drug Therapy for Seizure Control

The pharmacotherapy for termination of CSE begins with administration of IV lorazepam (LOR). The efficacy and safety of LOR in different care environments is supported by available evidence. In childhood SE the proportion of patients achieving clinical seizure control within 10 min of LOR administration has been consistently between 60% and 80%. In case of nonavailability of LOR, alternative benzodiazepines for IV administration as the first drug in SE include midazolam (MDZ) and diazepam (DZP). Recently, however, among children aged 3 months to ≤18 years, IV-LOR was not found to be superior to IV-DZP for cessation of CSE for 10 min without recurrence within 30 min. This primary end-point was met in 101/140 (72.1%) in the DZP group and 97/133 (72.9%) in the LOR group, with an absolute efficacy difference of 0.8% (95% CI −11.4% to 9.8%).

There is lack of systematic class I evidence for the management of CSE beyond the administration of the first benzodiazepine and there is considerable variability in practice. A majority of published protocols recommend fosphenytoin (FOS) or phenytoin (PHT) in case FOS is not available, as the second drug in sequence. The choice for third drug, after LOR and FOS/PHT is even more variable. Conventionally phenobarbital (PHB) has been used at this place. However, other choices include valproic acid (VPA), levetiracetam (LEV) and even lacosamide (LAC). Some neurocritical care experts recommend moving on to refractory SE protocols at this stage, i.e., after LOR and FOS.

At all steps of management of SE, the choice of drugs should incorporate patient specific factors, for example, avoiding

additional dose(s) of LOR in children who have already received a benzodiazepine within 1–2 hours of presentation, avoiding VPA in children less than or equal to 2 years already on multiple AEDs, or in those suspected to have an organic acid or urea cycle disorder, or preferring LEV in oncological patients with complex therapeutic regimens in view of lack of drug interactions with LEV. Children known to have epilepsy and already receiving AEDs on a chronic basis, present another management challenge. Particularly in children who are taking one of the medications used for treatment of SE, i.e., PHT, VPA, LEV or LAC, effort should be made to ascertain the adherence and total daily dose. Depending on these factors, the treating physician has to make an assumption about the blood level(s) of the chronic medications, till the reports are available. If the physician believes the drug levels to be appropriate, another drug with a different mechanism of action should be preferred. However, if drug levels are expected to be sub-therapeutic, the same medication can be given often using half the conventional dose.

It is important to have a written protocol for management of CSE which is thoroughly familiar to physicians on the emergency medicine, neurology, neurocritical care, and pediatric intensive care services, and is periodically reviewed and updated. A general protocol is provided **(Flow chart 1, Table 1)**. The clinical pharmacology of drugs used in the management of early and established SE are also reviewed briefly **(Table 2)**. These protocols should be regarded as broad guidelines and must be adapted to the needs and resources of a particular healthcare facility.

Nonvenous Routes
As mentioned above, establishing adequate IV access in a convulsing child is challenging and not always possible. Further, the IV route for administration of initial benzodiazepine is often not feasible in the out-of-hospital setting. Hence, attempts have been made to administer various benzodiazepines [LOR, DZP, midazolam (MDZ)] and paraldehyde (PLD) by nonvenous routes including rectal (PR), intranasal (IN), buccal (BC), and intramuscular (IM) routes. The specific route and drug combinations used in various RCTs have included PR-DZP, IN-MDZ, BC-MDZ, IM-MDZ, IN-LOR and IM-PLD. A Bayesian network meta-analysis has shown IN-MDZ to be superior to other route-drug combinations in terms of following outcomes: proportion of patients with seizure cessation within 10 min of drug administration, and persistent seizure cessation for at least 1 hour after drug administration. Specifically, the proportion of patients with seizure cessation within 10 min of IN-MDZ administration was found to be 90.3% (78.8–97.0%, pooled event rate using posterior distribution with 95% credible intervals). Further, the time to seizure termination after IN-MDZ administration was found to be 2.9 (1.8–4.1) min (pooled effect size, 95% credible intervals) [Arya, unpublished data]. Additionally, a recent RCT has compared prehospital administration of IM-MDZ and IV-LOR by paramedics. At the time of arrival in the emergency department, seizures were absent without rescue therapy in 329/448 (73.4%) of patients who received IM-MDZ compared to 282/445 (63.4%) of those who received IV-LOR, with similar adverse event rates in the 2 groups. In clinical practice, the decision to use a particular route-drug combination is usually determined by availability, ease-of-use, social acceptability and physician familiarity.

CLINICAL EVALUATION
In patients with new-onset SE, a detailed evaluation for the underlying cause is usually deferred till after stabilization and seizure termination. However, once the initial management targets are achieved it is pertinent to obtain a fairly detailed history, usually from family and/or bystanders, and perform a diligent examination to facilitate subsequent work-up.

The specific historical details should include information about any pre-existing chronic diseases, intercurrent illness, fever, head trauma, and any medications that the patient is receiving. Additionally, in patients known to have epilepsy, details of treatment, adherence and exposure to known triggering factors should be elicited. The specific circumstances of seizure onset can sometimes suggest the specific cause, e.g., an envenomation. General examination should include inspection of skin for pallor, cyanosis, icterus, cherry red discoloration, needle marks or any rash. Occasionally, general examination may also reveal stigmata of chronic underlying medical conditions. Systemic complications of status epilepticus are listed in **Table 3**.

The neurological examination should carefully document the level of consciousness. In children, it is often helpful to document the actual activity observed, in addition to a score on a coma scale. The cranium should be evaluated for any evidence of injury including local bruises, edema, bleeding from external auditory meatus, Battle's sign and cerebrospinal fluid otorrhea or rhinorrhea. Cranial nerve exam should focus on pupils and their reactions, fundus oculi, ocular position at rest, spontaneous and elicited eye movements. The occurrence of nystagmus requires fixation, hence, it is a clinical dictum that nystagmus in an unconscious patient represents seizure activity until proven otherwise. Motor examination should look for any asymmetry in posture or spontaneous movements, and decerebrate or decorticate posturing. Evidence for meningeal irritation and raised intracranial pressure (ICP) should be actively sought for. In this regard, absence of papilledema does not conclusively rule out raised ICP in children.

Continuous EEG monitoring and neuroimaging, preferably magnetic resonance imaging (MRI) of the brain are the two most important investigative modalities. It is often valuable to communicate with the radiologist about the specific clinical question(s) that are being sought from the imaging, e.g., contrast administration may be considered to increase the yield for certain infections, or susceptibility weighted sequences may be necessary if hemorrhage is suspected, and so on. Further details of the clinical utilization of these tests and role of other specific investigations are beyond the scope of this chapter.

REFRACTORY STATUS EPILEPTICUS
While there is no standard definition for refractory SE, most care environments and research publications have used variations on the following two criteria: (1) a convulsive seizure lasting longer than 60 min, which may be continuous or intermittent without return to baseline mental status; and/or (2) an acute convulsive seizure that is refractory to more than or equal to two classes of anti-seizure medications. At present, it is believed that the underlying etiologies for refractory SE are similar to those for impending, early and established CSE. However, as has been seen specifically in patients with febrile SE, a treatment delay may lead an established CSE to progress to refractory SE. In this regard, it is pertinent to differentiate refractory SE occurring in a patient with known pre-existing epilepsy from that occurring in the context of an acute encephalopathy. As mentioned earlier, this acute encephalopathy may be traumatic, infectious, vascular, immune, multifactorial, or may remain undiagnosed. Some of these patients with new-onset refractory SE (so-called NORSE) are increasingly being recognized to have autoimmune encephalitis.

Drug Therapy of Refractory Status Epilepticus
At this time, there are no randomized trials to guide treatment recommendations for refractory CSE. However, the two most commonly used regimens in children include continuous infusion of either MDZ or pentobarbital. By the time these coma inducing medications are considered, patient should have been intubated and managed in intensive care unit with skilled ventilatory care. Following is a brief review of some of the medications used in the

Flow chart 1 Management of status epilepticus in children older than 29 days (the protocol developed by Cincinnati Children's Hospital Medical Center Status Epilepticus committee and the Division of Emergency Medicine)

- Establish ABCs (maintain airway, provide oxygen, support vert ventilation as needed)
- Attach patient to monitor and pulse oximetry
- Obtain IV/IO access: Obtain finger-stick blood suger, I-stat and red top (to be sent for AED levels if applicable)
- Correct hypoglycemic, hyponatremia and/or hypocalcemia, as indicated

if having IV/IO access, give lorazepam 0.1 mg/kg push (max 4 mg)
If no IV/IO access, give midazolam 0.2 mg/kg Buccal/IN/IM (max 10 mg)

Seizure abates

Continue close observation
Ensure adequate oxygenation
Manage airway as clinically indicated
Consider I-stat to re-measure PCO_2
Discuss further management with neurology

Still seizing after 5 min

If having IV/IO access, give lorazepam 0.1 mg/kg push
If no IV/IO access, give midazolam 0.2 mg/kg Buccal/IN/IM
Page neurology consult fellow

Still seizing after 5 min

Other considerations:
1. If already received dose(s) of benzodiazepine (s) at home or via EMS; then only give 1 dose in ED before proceeding to fosphenytoin box
2. Valproate is associated with birth defects (pregnancy category D): recommend negative pregnancy test before giving in adolescent females

Consider IV glucose (avoid in patient on ketogenic diet), naloxone or pyridoxine based on clinical scenario if seizure refractory therapy

Strongly consider EEG if concern for subclinical status

Home AED therapy will not change acute management of status epilepticus except for known contraindication(s) for recommended therapies (examples: allergy, fosphenytoin for Dravet's syndrome, IV glucose for ketogenic diet)

Load with fosphenytoin 20 mg/kg IV via infusion over 15 min
(If fosphenytoin contraindicated: valproate 20 mg/kg IV via infusion over 10 minutes or phenobarbital 20 mg/kg via infusion over 20 min)

Still seizing 10 min after infusion is complete

Load with phenobarbital 20 mg/kg IV via infusion over 20 min
(If phenobarbital contraindicated: levetiracetam 50 mg/kg IV via infusion over 5 minutes or valproate 20 mg/kg IV via infusion over 10 min)
Page PICU fellow

Still seizing 10 minutes after infusion is complete

Start pentobarbital 5 mg/kg bolus, then 1 mg/kg/hour IV infusion
Perform endotracheal intubation if not already done

Abbreviations: ABC, airway, breathing, and circulation; AED, antiepileptic drug(s); ED, emergency department; EEG, electro-encephalography; EMS, emergency medical services; IM, intramuscular; IN, intranasal; IO, intraosseous; IV intravenous; PICU, pediatric intensive care unit.

treatment of refractory SE in children with some suggestions for clinical use **(Table 4)**.

Midazolam It acts by positive allosteric modulation of gamma-aminobutyric acid (GABA)-A receptors, is hydroxylated in the liver, and the metabolite undergoes renal excretion. Hence, MDZ levels may be affected by other medications, and hepatic or renal dysfunction. In pediatric case series, it has been found to achieve clinical and electrographic seizure control in 70–95% of instances. There is some evidence that rapid escalation of infusion rate may be more efficacious. Recurrent and breakthrough seizures are frequent (45–65% of episodes). MDZ only rarely induces hypotension by itself.

Pentobarbital It also depresses neuronal excitability by enhancing GABA-coupled responses. It is the first metabolite of thiopental,

which is available itself in some countries. Due to high lipid solubility, it is prone to accumulation with prolonged administration. It is often considered the treatment of choice for refractory SE in advanced care settings, due to significantly lower incidence of short-term treatment failure, breakthrough seizures or need to change to a different medication. Besides respiratory depression, pentobarbital is associated with negative inotropic effect and low cardiac output, causing significant hypotension. Thus, it is imperative to institute continuous blood pressure monitoring in patients on pentobarbital infusion, preferably invasive monitoring via an arterial catheter. Pentobarbital is also associated with increased risk of nosocomial infection, due to an immunosuppressive effect.

High-dose phenobarbital Very high doses of PHB (60–80 mg/kg/day) administered with an objective to attain serum levels more

Table 1 Management approach for status epilepticus

Time (min)	Drug therapy	Medical therapy
0–5	IV LOR (repeat PRN x2)	• Establish A, ensure B & C • IV access • Initiate cardiorespiratory monitoring • Order: Glucose, ABG, Na, K, Ca, CBC, BMP, AED levels • IV dextrose, fluids
5–30 (Early)	IV FOS/PHT	• Continue cardiorespiratory monitoring and support • Initiate CEEG monitoring • Identify and treat ABG/electrolyte disturbances
30–60 (Established)	IV PHB/VPA/LEV	• Identify and treat complications of etiology or SE *per se* • Consider IV pyridoxine in an infant with no obvious cause • Consider empiric antibiotics if febrile • Consider imaging
≥ 60 (Refractory)	MDZ/pentobarbital infusion	• PICU (if not already) • Assisted ventilation, vasopressor support

Abbreviations: A, airway; ABG, arterial blood gases; AED, anti-epileptic drug(s); B, breathing; BMP, basic metabolic panel; C, circulation; CBC, complete blood count; CEEG, continuous EEG; FOS, fosphenytoin; IV, intravenous; LEV, levetiracetam; LOR, lorazepam; MDZ, midazolam; PHB, phenobarbital; PHT, phenytoin; PICU, pediatric intensive care unit; VPA, valproic acid.

than or equal to 1,000 μmol/L, have anecdotal evidence for rapid control of refractory SE in children. Most of the case series report that hypotension was unusual and often mild.

Propofol It is an IV anesthetic that acts by a similar GABA modulation mechanism. It is rapidly acting (burst suppression within 30 min in nearly 70% of instances) and allows easy titration. However, with prolonged administration the terminal half-life may increase to several days. It is often avoided in children due to association with so-called *propofol infusion syndrome* characterized by cardiac failure, rhabdomyolysis, metabolic acidosis, renal dysfunction and sometimes death. Some of the factors reported to be associated with increased risk of this syndrome include: high dose of propofol, prolonged use, co-administration with catecholamines or corticosteroids, and a low body mass index. Additionally, increased mortality has been reported with propofol administration in children on ketogenic diet. Although some recent observations have challenged these concepts, there is reluctance in using propofol in children with refractory SE given that it is not known to be more effective than other medications, but may potentially have higher risks and higher mortality.

Inhaled anesthetics There is limited experience with rapid induction of dose regulated burst suppression using isoflurane and desflurane in children with refractory SE. However, all patients have been reported to develop hypotension requiring vasopressors and several had atelectasis, infections, paralytic ileus, or deep vein thrombosis.

Table 2 Clinical pharmacology of drugs used in the treatment of early and established status epilepticus

Drug	Dose (mg/kg)	Maximum single dose	Adverse effects with acute usage	Comments
Lorazepam	0.1	4 mg	Respiratory depression, hypotension, sedation	May be a delay in the onset of action by upto 2 min Has a redistribution time of 2–3 hours
Diazepam	0.2–0.5	20 mg	Similar to lorazepam	Although the elimination t ½ is ~24 hours, it gets quickly redistributed within 15–20 min For rectal administration, age and weight dependent dosing is used in pediatric patients
Midazolam	0.2–0.3	10 mg	Similar to lorazepam	
Phenytoin	20		Ataxia, nystagmus, dizziness, hypotension, QT prolongation, cardiac arrhythmias, local tissue reaction	Dose-dependent elimination with saturable metabolism, cautious use in children already on maintenance phenytoin Solvent for injection should be glucose free Slow infusion (1 mg/kg/min, up to maximum of 50 mg/min)
Fosphenytoin	20 (measured in phenytoin equivalents)		Rare hypotension	Phosphate ester pro-drug of phenytoin, well absorbed by intramuscular route Can be infused intravenously more rapidly compared to phenytoin, (3 PE/kg/min up to a maximum rate of 150 PE/min)
Valproic acid	15–20		Sedation, hyperammonemia, disturbed liver function	Infusion rate 3–6 mg/kg/min Caution with use in age ≤ 2 years or in women of childbearing age given teratogenic risk
Phenobarbital	20		Sedation, respiratory depression, hypotension	Infusion rate < 100 mg/min Long elimination half-life
Levetiracetam	20			Can be rapidly infused over 5 min Minimal drug interactions
Lacosamide	10–15	200 mg	Cardiac rhythm disturbances including increased PR interval	Limited information on efficacy in status epilepticus Minimal drug interactions
Pyridoxine	100 mg*		Apnea, bradycardia	Used in children ≤ 2 years of age with SE of unknown etiology Given as a bolus under EEG monitoring

*Not mg/kg

Table 3 Systemic complications of status epilepticus

System	Complications
Respiratory	• Apnea (acute apnea after a prolonged seizure without antecedent abnormal breathing pattern may at times suggest a rapidly evolving posterior fossa lesion)
	• Abnormal breathing patterns: may cause ineffective ventilation to the point of respiratory acidosis
	– *Cheyne-Stokes breathing:* Waxing waning hyperpnea, regularly alternating with shorter period of apnea; may be seen in massive supratentorial lesion(s), deep-seated cerebral or diencephalic lesions, e.g., subdural hematomas, infarcts, or meningitis, and certain metabolic disturbances. Important to rule out coexistent pulmonary disease
	– *Central neurogenic hyperventilation:* Suggests a lesion in lower mid-brain and/or upper pons; important to differentiate from hyperventilation due to medical reasons, e.g., Kussmaul breathing of metabolic acidosis
	– *Apneustic breathing:* Usually seen with low pontine lesions, e.g., basilar artery occlusion
	– *Chaotic irregularly interrupted breathing rhythm:* Each breath varying in depth and rate, may suggest a lesion of dorsomedial part of medulla
	• Aspiration
	• Airway compromise (secretions, hypotonia of tongue and/or oropharynx)
	• Noncardiogenic pulmonary edema
Hemodynamic	• Cardiac rhythm abnormalities (bradyarrhythmias seen more often)
	• Cardiac failure
	• Shock
Muscle breakdown	• Myoglobinuria (may cause oliguria or acute tubular necrosis, consider urinary alkalization, if myoglobinuria is detected or serum creatine kinase is more than 10 times upper limit of normal)
	• Hyperkalemia
Electrolyte abnormalities	• Hypoglycemia
	• Hyponatremia
	• Metabolic acidosis
Acute neurological	• Cerebral edema
	• Central hyperthermia

Table 4 Drugs used in the treatment of refractory status epilepticus

Medication	Initial bolus dose	Initial infusion rate	Maximum infusion rate
Midazolam	0.1–0.5 mg/kg	1–2 µg/kg/min	30 µg/kg/min
Pentobarbital	5–10 mg/kg	0.5–1 mg/kg/hour	3 mg/kg/hour
Propofol	2–5 mg/kg	1–2 mg/kg/hour	10 mg/kg/hour
Isoflurane		End-tidal concentration 1–1.2%	End-tidal concentration 5%
Ketamine	1–2 mg/kg	1–2 mg/kg/hour	5 mg/kg/hour
Valproic acid	20–40 mg/kg	5 mg/kg/hour	N/A
Topiramate	No intravenous formulation. Used via nasogastric route from 300 mg/day to 1,600 mg/day		
Levetiracetam	Not used as an infusion. Total dose of 15–60 mg/kg/day is split in 1–2 daily doses.		

Ketamine As a noncompetitive N-methyl-D-aspartate (NMDA) glutamate receptor antagonist, ketamine may be effective in refractory SE, when there is GABA receptor endocytosis leading to decreased efficacy of GABA modulating drugs. It may also be neuroprotective by reducing NMDA-mediated glutamate excitotoxicity. Further, it may improve cerebral perfusion by increasing blood pressure due to its sympathomimetic properties, as compared to most other medications used in the treatment of refractory SE which are prone to cause hypotension. However, cerebellar toxicity with prolonged administration is recognized.

Other medications Although not considered as specific treatments for refractory SE, some of the other medications also have variable anecdotal evidence for control of refractory SE in children. These medications include: VPA, TPM, LEV, adrenocorticotrophic hormone (ACTH) and corticosteroids. These medications may be useful in specific clinical situations, particularly where successful intubation is unlikely, as there is lower risk of respiratory failure with these drugs compared to other regimens. Corticosteroids and ACTH may be useful in patients with suspected or proven autoimmune causes for their refractory SE.

Nonpharmacological treatments Dietary and neurosurgical treatments have been successfully tried in selected children with refractory SE. Ketogenic diet is a high-fat, low-carbohydrate diet with proven efficacy in certain inborn errors of metabolism associated with epilepsy and some drug-resistant epilepsy syndromes. It has been tried in children with refractory SE via modified parenteral nutrition solutions or rarely via gastric tube, with limited success. Regarding epilepsy surgery, both resective and palliative procedures have been used in refractory SE with success being driven by patient selection. The principles of presurgical evaluation and surgical decision making are similar to the patients undergoing more deliberate evaluation, and rely on concordance of multiple modalities. If facilities for epilepsy surgery exist, a consultation with an epileptologist is desirable earlier in the management of refractory SE. Further details about epilepsy surgery for refractory SE are beyond the scope of this chapter.

Although controlled hypothermia has been demonstrated to be beneficial in adults after cardiac arrest and neonatal encephalopathy, its role in pediatric refractory SE is not well defined.

Continuous Electroencephalography Monitoring

Children in refractory SE lack easily measurable indices of function and the bedside exam is often unreliable due to the disease process itself and drug therapy. Optimal management of refractory SE requires continuous EEG monitoring, which may not always be feasible in RPCs. It has been shown that EEG detects neuronal dysfunction at a reversible stage providing a therapeutic window. Further, it has been shown that about a third of patients may continue to have electrographic seizures after no clinical seizure activity is obvious. There is both laboratory and clinical evidence that such continued electrographic seizures adversely influence prognosis. If available, patient should be hooked up to the EEG during established or early refractory stages of SE. Regular 21

electrode placement is recommended unless precluded by head trauma. Perhaps the most controversial aspect of the management of refractory SE is the treatment end-point. There is no consensus regarding suppression of only seizures, or suppression of bursts, and if so the degree and duration of suppression. At our institution, we allow for up to 10s of burst(s) every 3 EEG epochs, i.e., 70% suppression, for at least 24 hours and often 48 hours. During this time we review the EEG frequently using both visual analysis and quantitative methods, and modify drug therapy accordingly. Continuous EEG monitoring can also help inform the prognosis with excessive discontinuity or lack of reactivity being suggestive of poor prognosis, whereas progressive EEG improvement with treatment and preserved N2 sleep markers, or evidence of state cycling usually forecasting relatively better outcomes.

Super-refractory Status Epilepticus

When SE continues or recurs despite 24 hours of IV or inhalational general anesthesia, it is termed super-refractory SE. It usually pertains to electrographic nonconvulsive SE noticed on attempting to wean off coma inducing medications. Often, management of super-refractory SE requires continued use of general anesthesia for prolonged periods, at times up to many weeks, with intermittent attempts at weaning under EEG monitoring with simultaneous optimization of maintenance antiseizure medications. Management of concurrent medical complications is complex and individualized. At a minimum, it requires daily attention to pulmonary toilet, fluid management, bowel, bladder and skin care.

Suggestions for Practice

The management of refractory SE in a resource-limited environment should be based on available facilities. In both literature and clinical practice, 2 trends are noticeable: firstly, earlier use of coma protocols often after IV-LOR and FOS; and secondly, preferred use of pentobarbital over MDZ. These trends may not be applicable in most RPCs. Thus, if facilities for adept intensive care are not readily available, there may be value in trying VPA, LEV, TPM or high-dose phenobarbital, before deciding about coma induction. It should be recognized that almost all patients will require some respiratory support during late established or refractory stages of SE. The important consideration at this stage is to prevent hypotension, which can cause secondary brain injury by compromising cerebral perfusion in a setting of sub-optimal autoregulation. Hence, if invasive vascular monitoring and targeted hemodynamic management is not available, MDZ infusion may be tried first, with rapid escalation of infusion rate **(Table 4)**. There should be simultaneous efforts to optimize maintenance antiepileptic drug therapy, because MDZ tachyphylaxis will set-in with continued use. Having attained treatment end-point for 24–48 hours, the infusion should be gradually decreased with continued monitoring for seizures. Again, there is lack of consensus about the management of electrographic seizures seen during this phase. We usually tolerate up to several seizures per day, and do not regard shorter emergent EEG bursts as necessarily associated with poor outcomes. The distinction between refractory SE and SE of shorter duration is the degree of morbidity and mortality associated with the former, which results from a combination of the severity of the underlying disease, the neurological and systemic complications from the prolonged seizure **(Table 3)**, and the adverse effects of the medications needed to control the seizures.

OUTCOMES

Interim Complications

Repeated or prolonged seizures cause several pathophysiological changes that can contribute to morbidity and mortality. In patients with established SE or beyond, it is important to diagnose and appropriately manage these systemic complications **(Table 3)**.

Long-term Outcomes

Status epilepticus is associated with considerable short-term (during hospitalization or within 30 days of SE) and long-term (within 10 years following initial survival 30 days after SE) mortality. Several cohort studies have found age and etiology to be major determinants of both short-term and long-term mortality in SE. A systematic review found mortality to be lower in children as compared to adults and elderly, with short-term mortality up to 9% and long-term mortality up to 7%. Amongst children, infants less than or equal to 1 year of age had the highest short-term mortality, up to 18%. Most deaths during hospitalization for SE or within 30 days of onset of SE have been noted to occur in children with acute symptomatic etiology. In a cohort study from Kenya, 23% of children with confirmed CSE died before discharge, and 18% were left with neurological sequelae. Of the children who died during hospitalization, 75% of the deaths were with 48 hours of onset of SE.

Neurological sequelae of CSE also have been noted to be age dependent with relatively higher incidence in infants. In a large prospective study with mean follow-up of 13.2 months, the incidence of neurological deficits attributable to CSE was 29% in infants less than or equal to 1 year of age, 11% in children 1–3 years of age, and 6% in children more than 3 years of age.

IN A NUTSHELL

1. Status epilepticus in adults and children more than or equal to 5 years of age is defined as: more than or equal to 5 min of continuous seizures, or more than or equal to 2 discrete seizures without complete recovery of consciousness in between, or presentation to the emergency room in active convulsion.
2. Prolonged febrile seizures constitute the most common subgroup of childhood status epilepticus. In resource poor countries, neurological and systemic infections are also significant contributors, the exact nature of infectious agents being governed by local epidemiology.
3. Recent large multicenter study on febrile status epilepticus has shown that delayed initiation of treatment is associated with increased duration of status epilepticus.
4. Several targets have to be simultaneously addressed to optimize the outcome of a child with CSE: support of critical physiological functions (airway, breathing and circulation) to ensure adequate brain oxygenation and perfusion, termination of clinical and electrical ictal activity, identification and management of precipitating factors, and prevention and treatment of systemic complications of status epilepticus. In a subgroup of patients, it is also pertinent to attempt identification and initiate management of the underlying disease process.
5. Status epilepticus is associated with considerable short-term and long-term mortality, with age and etiology being significant predictors of outcome.

Chapter 42.12
Nonepileptic Paroxysmal Disorders
Hema Patel, David W Dunn

Paroxysmal nonepileptic disorders are frequently encountered in children and can often be mistaken for seizures. Up to 20–25% of patients referred to epilepsy centers with the diagnosis of seizures may have nonepileptic events. It is important to distinguish between paroxysmal events and to avoid inappropriate, expensive evaluations, unnecessary hospitalizations and emergency room visits. An accurate diagnosis can be made for the majority of these cases by a detailed history. Additional diagnostic procedures will usually not be necessary. A classification based on age of onset of these nonepileptic disorders is given in **Table 1** and some of the more common nonepileptic disorders occurring in different age groups are reviewed.

NEONATES AND INFANTS

Tetany

Tetany is characterized by involuntary movements and systemic symptoms and signs. It may be seen in infants near the end of the first week of life that are being fed cow's milk. These infants have hyperexcitability with tremors and muscle spasms. It is due to hypocalcemia and possibly hypomagnesemia. Untreated it may progress to convulsions. Tetany may also be seen in older infants and children. The spasms involve hands characterized by adduction of the thumb and flexion of the fingers (carpopedal spasms) and feet and occasionally laryngospasm. Tapping over the peroneal nerve may cause spasms in the foot and tapping over the facial nerve, contractions in the face (Chvostek sign). Possible etiologies include hypoparathyroidism, renal disease, and vitamin D deficiency.

Breath-holding Spells

Breath-holding spells may be cyanotic or pallid. Cyanotic breath-holding spells are more common. Family history of similar episodes is positive in 23–38%, suggesting a genetic influence, with an inheritance consistent with an autosomal dominant pattern with incomplete penetrance. Details are given in Section 21. Breath-holding spells can be diagnosed based on a history of a precipitating event, which may even be minor, and the characteristic clinical description of the episode. No laboratory tests are needed. A home video of the episode may be helpful. EEG is not indicated unless diagnosis is in doubt and epileptic seizures cannot be conclusively ruled out. If performed, it may reveal slowing or suppression of the background and absence of epileptiform discharges. It is important to differentiate breath-holding from seizures to avoid unnecessary treatment with antiepileptic drugs **(Table 2)**. The brief convulsive movements seen during breath-holding spells are reflex anoxic seizures and are not epileptic.

Shuddering Attacks

Shuddering attacks usually present in infancy at 4–6 months of age, rarely occurring after the age of 3 years. The attacks usually last for a few seconds. They are characterized by rapid tremor or shivering of the body with sudden flexion of head, trunk and elbows, adduction of elbows and knees and no alteration of consciousness. This activity is similar to shivering that occurs when exposed to cold. The episodes occur in clusters, several times a day. The pathophysiology is not known. Differential diagnosis includes infantile spasms or generalized seizures. The EEG is normal. Parents need to be reassured that this is a benign, self-limited condition and no treatment is necessary.

Benign Myoclonus of Infancy

This is characterized by sudden onset of clusters of brief myoclonus or tonic contraction of the head, neck, trunk and extremities seen in developmentally normal infants, 1–12 months of age. The activity resembles infantile spasms, but the neurologic examination and EEG are normal. The etiology is not known. Prognosis is excellent, with the activity usually resolving by 2 years of age. No specific treatment is needed.

Table 1 Nonepileptic paroxysmal disorders classified by age of onset

Age	Disorder
Neonates	Jitteriness Hyperekplexia Benign neonatal sleep myoclonus Tetany
Infants (2 months to 2 years)	Breath-holding spells Shuddering attacks Benign myoclonus of infancy Sandifer's syndrome Spasmus nutans Paroxysmal tonic upgaze of childhood Self-stimulatory behavior Stool-withholding activity Rhythmic movement disorder Hyperekplexia Alternating hemiplegia of childhood
Children (2 years to 12 years)	Stereotypies Tics Parasomnias Migraine and variants [cyclic vomiting, benign paroxysmal vertigo (BPV)] Paroxysmal dyskinesias Gastroesophageal reflux disease (GERD) Self-stimulatory behavior Stool-withholding activity Munchausen by proxy Hypnic jerks
Adolescents (12 years)	Psychogenic nonepileptic seizures (PNES) Syncope Migraine and variants Narcolepsy Tics Paroxysmal dyskinesias Transient global amnesia

Table 2 Differences between breath-holding spells and epileptic seizures

	Breath-holding spells	Epileptic seizures
Triggering factors	Crying, injury	Spontaneous, sleep deprivation, fever
Occurrence in sleep	No	May occur
Description	Provocation followed by apnea and cyanosis or pallor and limpness	Tonic (stiffening) and clonic (jerking) of extremities
Postictal state	Brief	Usually prolonged
EEG	Generalized slowing or suppression of background	Epileptiform abnormalities
Treatment	Reassurance	Antiepileptic drugs

Sandifer's Syndrome

Gastroesophageal reflux disease (GERD) in babies and children may be associated with back arching that occurs after feeding. Sandifer's syndrome is a rare syndrome that was previously described in association with hiatal hernia, but is more commonly associated with GERD. It is characterized by tonic neck extension, deviation of the head to one side (*spastic torticollis*) and dystonic posturing of the trunk. The abnormal posturing is thought to be secondary to discomfort associated with reflux. Onset is usually in infancy or early childhood. This syndrome is differentiated from other causes of torticollis such as posterior fossa tumors, cervical vertebrae abnormalities, or seizures based on its intermittent occurrence with relation to feeding or the postprandial period. The symptoms resolve with treatment of reflux.

Spasmus Nutans

This syndrome is characterized by a triad of head nodding, head tilt or torticollis and nystagmus. It usually begins at 4–12 months of age and remits within 1 or 2 years from onset. Nystagmus is typically horizontal and may be more prominent in one eye. Symptoms may fluctuate throughout the day and are not associated with alteration in level of consciousness. Evaluation should include neuroimaging studies of the brain, because some cases have been associated with lesions in the optic chiasm or third ventricle. No specific treatment is indicated because the condition is benign and self-limiting. Most patients will develop good visual acuity. Subclinical nystagmus may persist until 5–12 years of age.

Paroxysmal Tonic Upgaze of Childhood

Onset is usually in the first year of life, occasionally even in the first few weeks. It is characterized by brief, conjugate upward eye deviation lasting from seconds to minutes with incomplete downward saccades on attempted downgaze and compensatory neck flexion. Horizontal eye movements are normal. These episodes resolve over a few years. Ataxia, learning disabilities, cognitive deficits and pervasive developmental disorder have been reported in some cases. Evaluation is normal including spinal fluid and metabolic studies. Differential diagnosis includes oculogyric crisis, seizures and brainstem disorders. Medications are unnecessary because these paroxysmal episodes are brief and self-limiting and resolve over years. However, ataxia may persist as a permanent disability.

Self-stimulatory Behavior

Self-stimulation is masturbatory behavior that occurs in infants and young children. These are stereotypic episodes of genital self-stimulation, characterized by tightening and rubbing of the thighs with pressure to the pubic and suprapubic area and rhythmic pelvic thrusting. These rhythmic, rocking movements may last for minutes to hours, and are often associated with irregular breathing and flushing, and it may require a lot of effort to distract the child. These episodes may be mistaken for abdominal pain, dystonia or seizures, resulting in unnecessary evaluation. Treatment includes parental reassurance that the episodes are benign and self-limiting. The term *gratification behavior* may be more acceptable because parents may be upset by the term *masturbation*.

Stool-withholding Activity and Constipation

The child may exhibit episodic, abnormal behavior as a way to prevent the painful passage of hard stool because of chronic constipation. It is characterized by sudden interruption of activity with assumption of a motionless posture of slight truncal flexion, occasionally with brief generalized jerks, due to discomfort associated with withholding stool. This behavior may be mistaken for tonic seizures. Treatment of the chronic constipation causes resolution of this behavior.

CHILDREN

Stereotypies

Repetitive stereotyped, purposeless movements are commonly seen in neurologically impaired children with intellectual deficiencies and autism and may be mistaken for seizures. These include rhythmic movements such as head nodding, tongue thrusting, tonic posturing and self-stimulatory behaviors such as rhythmic head shaking, swaying and body rocking. Deaf or blind children frequently resort to self-stimulatory behaviors such as hitting their ears or poking at their eyes.

Other types of stereotypies include more complex motor behaviors with different movements in each episode that are not truly stereotypic. They consist of rhythmic, coordinated, repetitive and quasi-purposeful movements, most commonly affecting the upper extremities and head, such as hand rotation, arm flapping or head nodding. They are brief, lasting from seconds to few minutes, occur in clusters several times a day, are provoked by excitement, stress, fatigue and boredom, and are suppressible. They do not interfere with daily activities and do not occur during sleep. They usually start before 3 years of age. This behavior may not only be seen in children with intellectual deficiencies and autism, but also in those with normal development and intelligence. Comorbidities include learning disabilities, attention deficit hyperactivity disorder (ADHD), tics and obsessive compulsive disorder. Family history is present in 25% of cases. These movements are usually persistent, with resolution only in about 5% by 11–12 years of age. Pathophysiology is unclear. The cortico-striato-pallido-thalamic pathway is thought to be involved.

Diagnosis Stereotypies may be mistaken for tics. Clinical features differentiating the two are listed in **Table 3**.

Management Medications have not been successful in treatment of stereotypies. Behavioral therapy is frequently more successful than medications in controlling these movements.

Tics

Tics are sudden, brief, nonrhythmic, rapid, repetitive, involuntary movements that may be motor, vocal or both. They are associated with a premonitory feeling that is relieved by performing the tic, are aggravated by excitement and stress, and disappear during sleep.

Table 3 Differences between stereotypies and tics

	Stereotypies	*Tics*
Age of onset	Before 3 years	6–7 years
Description	Mostly stereotypic, patterned, predictable	Variable
Location	Arms	Facial muscles
Movements	Flapping, waving of upper extremities	Blinking, grimaces, shoulder shrugs
Rhythm	Rhythmic	Rapid, brief, nonrhythmic
Duration	Prolonged, continuous	Brief, intermittent
Premonitory urge	No	Yes
Triggering factors	Excitement, boredom, stress	Stress, anxiety, relaxation after stress
Suppression	Distraction	Brief, associated with increased urge to perform the tics
Treatment	Poor response	Neuroleptic medications

Efforts to suppress the tics volitionally result in an increasing urge to perform them, with relief after doing so. Motor tics are divided into simple and complex tics and most frequently involve the face, neck, and shoulders. Simple motor tics consist of sudden, brief, meaningless movements such as grimacing, blinking, head jerking, shoulder shrugs and jerks involving the arm or leg. Complex motor tics seem more purposeful, being characterized by activity such as chewing, jumping, hopping, tapping on or smelling objects or self. Vocal tics are also either simple or complex. Simple vocal tics include, throat clearing, coughing and grunting, and complex vocal tics include uttering words or profanities (coprolalia). Tics may be transient or lifelong.

Tourettes syndrome is an autosomal dominant disorder characterized by motor tics and vocalizations present for at least 12 months and is frequently associated with learning disabilities, ADHD, and compulsive behaviors. The disorder tends to be lifelong, though it may stabilize or improve in early adulthood.

Diagnosis Tics need to be distinguished from myoclonic seizures which are characterized by brief, isolated jerks of one or more extremities without associated change in consciousness, are not suppressible, and are associated with epileptiform abnormalities on the EEG.

Management Simple tics that are not disruptive may not require treatment. If they cause distress, effective medications include dopamine antagonist (risperidone, haloperidol), guanfacine and clonidine. Stimulants such as methylphenidate may exacerbate the tics, but may be used at half the usual starting dose without worsening tics in children with tics and ADHD.

Parasomnias

Parasomnias occur during all phases of sleep, including sleep onset (rhythmic movement disorder), non-rapid eye movement (REM) sleep (confusional arousals, night terrors and sleep walking) and REM sleep (nightmares, REM sleep behavior disorder). Rhythmic movement disorder includes head banging (jactatio capitis nocturna), body rocking and head rolling. These are repetitive, stereotypic movements involving the large muscles of the body, occurring during wake to sleep transition and may continue into light sleep. They are seen in infants and young children, peak at 18–24 months of age and usually subside by 5 years of age. They are more common in children with learning difficulties and intellectual disabilities. The bed should be padded to protect against injury. No specific treatment is indicated. However, clonazepam may be used for potentially injurious episodes.

Migraine and Variants (Cyclic Vomiting and Benign Paroxysmal Vertigo)

Migraine headaches are relatively common and may affect approximately 5% of children and 10–15% of adolescents. Some children, adolescents, or parents may be able to identify triggers such as foods, weather changes, menstrual cycle, or sleep irregularity. There are several migraine variants. Benign paroxysmal vertigo (BPV) occurs in preschool age children. These are brief episodes of vertigo without loss of consciousness. The child may fall or hold onto objects for support. Nystagmus may be noted during an episode. Cyclic vomiting presents as episodes of abdominal pain, nausea, and vomiting usually beginning prior to 5–6 years of age. The episodes may last up to 3–4 days and can cause dehydration. Cyclic vomiting may be one presentation of a mitochondrial disorder. Diagnosis and management of migraine are discussed in the chapter on headaches.

Paroxysmal Dyskinesias

These are rare disorders; four types have been described— paroxysmal kinesigenic dyskinesia (PKD), paroxysmal non-

kinesigenic dyskinesia (PNKD), paroxysmal exercise-induced dyskinesia (PED) and paroxysmal hypnogenic dyskinesia (PHD). Majority of the cases are of the PKD and PNKD type and are idiopathic (primary), but may be also be familial or symptomatic (secondary). They present from childhood through early adulthood.

Paroxysmal kinesigenic dyskinesia consists of brief attacks of choreoathetosis, dystonia or ballistic movements, that occur alone or in combination, can be unilateral or bilateral, with retained consciousness, and are precipitated by sudden change in movement or even an intention to move. They may be preceded by an aura of tightness or paresthesia in the involved extremities. The children have a normal neurologic examination between episodes. The condition is more common in boys than girls. It may be familial (autosomal dominant), idiopathic or secondary to conditions such as multiple sclerosis, stroke, or traumatic brain injury. Neuroimaging studies are normal, and no epileptiform changes are noted on the EEG during the episode if the disorder is familial or idiopathic. It responds very well to the antiepileptic drugs carbamazepine and phenytoin. The attack frequency decreases with age with complete remission in approximately 25% of cases.

Paroxysmal nonkinesigenic dyskinesia consists of spontaneous attacks of severe dystonia or choreoathetosis involving face, trunk and extremities, often associated with dysarthria and dysphagia, that may be precipitated by alcohol, caffeine, excitement, stress and fatigue. They last from few minutes up to several hours. Antiepileptic drugs are less consistently effective. They respond to clonazepam and diazepam. Prognosis is not as good as for PKD.

Paroxysmal exercise-induced dyskinesia consists of brief episodes of dystonia that occur after several minutes of exercise and not at initiation of movement as in PKD. The dystonic movement typically involves part of the body doing the most exercise and resolves gradually after cessation of the exercise. Acetazolamide has been effective in some cases.

Paroxysmal hypnogenic dyskinesia consists of brief dystonic episodes during or immediately after arousal from non-REM sleep. These episodes, though included in this classification, are nocturnal seizures seen in autosomal dominant nocturnal frontal lobe epilepsy.

Pathophysiology of paroxysmal dyskinesias is not completely understood. The etiology as with other periodic disorders is presumed to be channelopathies. However, many of the familial cases of PNKD are caused by mutation of myofibrillogenesis regulator 1 (MR-1) gene on chromosome 2, which is not involved with ion channels.

ADOLESCENTS

Psychogenic Nonepileptic Seizures

Psychogenic nonepileptic seizures (PNES) are episodic, behavioral spells that can be mistaken for true epileptic seizures. They may be due to an underlying psychological stressor or conflict. PNES have been referred to as hysterical epilepsy, pseudoseizures and nonphysiologic or functional seizures. The term PNES is preferred because it is neutral and not pejorative. PNES have been described extensively in adults but there are fewer reports in children. They account for 3.5–7% of children seen in the outpatient clinic for assessment of seizures. PNES commonly occur between 15 years and 35 years of age, but are seen in all age groups ranging from elementary-age children to the elderly. PNES is more common in females. This preponderance of females is more characteristic in adolescence than childhood. This sex-related trend is even more marked in adults, occurring in 75–80% of the patients.

Clinical features that help differentiate PNES from epileptic seizures are outlined in **Table 4**. In children younger than 13 years

Table 4 Differences between clinical features of psychogenic nonepileptic seizures (PNES) and epileptic seizures

	PNES	Epileptic seizure
Duration	Prolonged	Few minutes
Clinical features	Fluctuating features	Stereotypic
Time of day	Usually while awake with audience present	May occur during sleep
Consciousness during episode	Consciousness retained even with generalized activity Avoidance behavior	Impaired consciousness (except with supplementary motor seizures)
Onset	Gradual, slow escalation in intensity	Abrupt
Head movements	Mostly side to side	Usually head deviation to one side
Extremities	Out of phase movements	In phase movements
Pelvic thrusting	Forward	Retrograde
Vocalizations	Emotional (crying) during episode	Monotonous vocalization at onset
Eyes	Closed during episode	Usually open
Incontinence	Rare	May be present
Tongue bite	Rare, usually on tip	Common, usually on lateral margin
Related injury	Not consistent with fall	Is consistent with fall
Postictal change	Absent or brief, even after prolonged convulsive event	Prolonged with confusion, fatigue, drowsiness (may be absent after frontal lobe seizure)
Affect	La Belle indifference	Concerned

of age, PNES more commonly present as subtle motor activity such as eye fluttering, isolated head shaking, prolonged staring with unresponsiveness, generalized limpness and behavioral changes such as combativeness. In children 13 years and older, the clinical features may be similar to those seen in adults and are characterized by more prominent motor activity with generalized arrhythmic jerking or flailing of extremities, side-to-side head movements and forward pelvic thrusting.

The most commonly identified stressors in children include school difficulties (such as poor school performance, difficulty with learning), family discord (parental divorce, physical abuse, parental or sibling hostility, financial stress), interpersonal conflicts with peers or teachers, bereavement or concurrent personal or family illness. A history of sexual abuse is less frequent in children with PNES than in adults, ranging from 5% to 32% in different reports. Coexisting neurologic illness including headaches, learning disabilities and ADHD have been reported. 10–40% of patients with PNES also have epileptic seizures. Coexistent psychiatric disorders such as depression, anxiety disorders and borderline personality disorders are seen more commonly in adults, though children with PNES have more behavioral and emotional problems, such as mood disorder and anxiety disorders, than children in the general population. The prevalence of psychopathology associated with PNES is higher in the adolescent age group. Family history of epilepsy and somatization may serve as a behavioral model for children to shape expression of their own symptoms.

Diagnosis
It can be difficult to differentiate PNES from epileptic seizures based on clinical features alone. The diagnosis is often delayed for 6 months or more in children and even longer in adults. When the diagnosis is unclear, physicians may start antiepileptic drugs because they worry about not treating a child who might have epilepsy. Misdiagnosis can result in inappropriate and often costly treatment, unnecessary hospitalizations and iatrogenic complications such as invasive procedures in prolonged PNES (e.g., psychogenic nonepileptic status or pseudostatus epilepticus)

and adverse effects from antiepileptic drugs. More importantly, it results in patients not receiving much needed psychiatric treatment.

Evaluation should include a detailed description of the episode by an eye witness. A home video of the events may be very beneficial. Prolonged video-EEG remains the gold standard for definitively diagnosing PNES. A definitive diagnosis of PNES is made only if the recorded event is identified by the family as *the habitual event of clinical concern* and is not associated with epileptiform activity on the EEG. If multiple types of episodes are reported, all these different episodes should be recorded.

Management
It is important to convey the diagnosis to the family in an appropriate, understanding and non-judgmental manner without making them feel that the child is *faking it* or *is crazy*. Early diagnosis is essential to prevent the episodes from becoming the patient's primary coping mechanism for dealing with stress. The patient is referred to a trained mental health professional such as a psychiatrist or psychologist who is knowledgeable about PNES for evaluation and treatment of the underlying psychopathology. The patient is taught new coping skills and stress management techniques. Cognitive behavioral therapy has been found to be beneficial in adults. In some cases with uncomplicated histories, the PNES may resolve after explanation and education about the condition and once the patient and family accept the diagnosis. In patients who were mistakenly placed on antiepileptic therapy, these medications should be weaned slowly. It should be stressed that the physician will continue to maintain contact with the patient so that the family does not feel abandoned.

Syncope
Episodes of syncope are common in adolescents. Most episodes are due to vasovagal syncope caused by brief cerebral hypoperfusion. The episodes occur when the adolescent is awake and standing or, less often, sitting up. They are triggered by a sudden change in posture, pain such as blood drawing, or emotion. Prior to loss of consciousness, the adolescent may notice dizziness, sweating,

nausea, or a feeling of the environment becoming distant. After the event, there may be nausea and fatigue. Syncope may also follow hyperventilation, coughing, or a Valsalva maneuver or after periods of prolonged standing, possibly due to decreased venous return.

Cardiac syncope is less common. These episodes may occur during exertion, are seldom accompanied by symptoms before or after the events, and may occur when the adolescent is lying flat, sitting, or standing. Cardiac syncope may be the result of outflow obstruction, arrhythmia, or heart block.

Diagnosis

The diagnosis is based on the description of the episode. Brief myoclonic or clonic seizure-like activity may occur during vasovagal or cardiac syncope, particularly if the duration of syncope is long or if the adolescent is held upright. The triggering event helps distinguish syncope from seizures. If there is any question of a cardiac cause, an ECG should be obtained. EEG is rarely indicated, and should be performed only if there is no clear precipitant.

Management

Reassurance is helpful. Adolescents can also be advised to maintain adequate hydration and to lie down or do isometric muscle contraction for presyncopal symptoms.

IN A NUTSHELL

1. A detailed history is essential and necessary for the diagnosis of nonepileptic paroxysmal disorders.
2. Laboratory studies are not necessary for the majority of the nonepileptic paroxysmal disorders.
3. Video EEG remains the gold standard for distinguishing psychogenic nonepileptic seizures (PNES) from epileptic seizures.
4. Reassurance of parents is the key management strategy for most of these disorders.
5. Cognitive behavioral therapy may be helpful in PNES and possibly for frequent migraines.
6. Medications are available for treatment of tics, migraine, paroxysmal dyskinesias and parasomnias.

Chapter 42.13

Coma, Raised Intracranial Pressure and Brain Death

Gurpreet Singh Kochar, Suvasini Sharma

COMA

Coma represents severe derangement in consciousness resulting from diffuse and bilateral cerebral dysfunction, or failure of brainstem-thalamic ascending reticular activating system (ARAS). Evaluation of a comatose child requires a systematic approach with immediate evaluation and stabilization of vital functions, followed by appropriate diagnostic and urgent therapeutic interventions to prevent irreversible brain injury.

DEFINITIONS

Consciousness is the state of awareness of self and environment. There are two components of consciousness: (1) wakefulness or arousal, which is mediated by ascending reticular activating system (ARAS) and diencephalon; (2) awareness, which require functioning of both cerebral hemispheres. Evaluation of awareness in infants and children must take into account the age and appropriate developmental level.

Impaired states of consciousness are also sometimes classified as lethargy, stupor and coma. *Stupor* is a state of unresponsiveness from which the patient can only be aroused transiently by vigorous and repeated stimulation. *Coma* is a state of deep, sustained pathologic unconsciousness (lasting > 1 hour) with the eyes closed characterized by the total absence of wakefulness (absence of sleep wake cycles) and awareness. The motor response in comatose child may be variable. *Lethargy* describes state of alertness between alertness and stupor. Describing all the components used in the assessment of consciousness, e.g., eye opening, motor and verbal responses, awareness of self and environment and presence of sleep wake cycles in an individual patient gives better information rather than using these terms (lethargy, stupor or coma).

Coma is typically a transitional state, evolving toward recovery of consciousness, the vegetative state, the minimally conscious state, or brain death. *Vegetative state* is differentiated from coma by intermittent wakefulness manifested by the presence of sleep-wake cycles and sufficiently preserved hypothalamic and brain-stem autonomic functions to permit survival.

Minimally conscious state (MCS) is defined as a condition of severely altered consciousness in which the patient demonstrates minimal but definite behavioral evidence of self- or environmental awareness like following simple commands, yes-no response and some purposeful behavior (smiling, reaching out for object).

EPIDEMIOLOGY

The causes of coma are varied and complex, and are affected by geographic distribution, ethnic background and season. The causes can be broadly classified as coma with focal signs (structural brain disease) and coma without focal signs (diffuse brain disease); summarized in **Box 1**. Nontraumatic coma is discussed in this chapter. In developing countries, infection remains the leading cause of acute nontraumatic coma. In a review of 14 studies from resource poor countries (majority from Africa and Asia, including two studies from India), the three most common infections were cerebral malaria, acute bacterial meningitis and viral encephalitis. The most common viral agent reported in India from 1975 to 1999

BOX 1 Causes of coma in children

I *Coma with focal signs (Structural brain disease)*
- Head injury (accidental and nonaccidental head injury)
- Vascular
  - Arterial ischemic stroke or sinovenous thrombosis
  - Hemorrhagic stroke
- Mass lesions
  - Tumors
  - Abscess
  - Others (tuberculoma, hematoma)
- *Infections:* Meningitis (bacterial or tuberculous with vasculitis), Brain abscess
- *Post seizure state:* Todd's paralysis
- *Immune mediated:* Acute disseminated encephalomyelitis

II *Coma without focal signs*
- *Hypoxia-Ischemia:* Cardiac or pulmonary failure, cardiac arrest, shock, near drowning, carbon monoxide poisoning (gas geyser)
- *Metabolic disorders:* Hypoglycemia, hypernatremia, hyponatremia, acidosis, syndrome of inappropriate ADH secretion (SIADH), diabetes insipidus (DI)
- *Systemic infections:*
  - *Bacterial:* Gram-negative sepsis, meningitis, toxic shock syndrome, *Shigella* encephalopathy, enteric encephalopathy
  - Cerebral malaria
  - *Rickettsial:* Lyme disease, Rocky mountain spotted fever
  - *Tuberculous:* Tubercular meningitis
- *Postinfectious disorders*: Acute necrotizing encephalopathy (ANE), ADEM, hemorrhagic shock and encephalopathy syndrome (HSE)
- *Poisoning:* Drugs and toxins
- Systemic illness associated with coma
  - Hepatic encephalopathy
  - Renal failure
  - Diabetic ketoacidosis, hypoglycemia
- Inborn errors of metabolism
  - Urea cycle disorders
  - Aminoacidopathies and organic academia
  - Mitochondrial cytopathy
- Autoimmune
  - NMDAR antibody encephalitis, limbic encephalitis
- Idiopathic status epilepticus (particularly nonconvulsive); acute epileptic encephalopathies (FIRES, fever-induced refractory epileptic encephalopathy in school-aged children).

---

was Japanese encephalitis but studies published after the year 2000 identified enteroviruses and chandipura viruses to be the most common. The noninfectious causes of nontraumatic coma reported from various studies included toxic-metabolic (Reye's syndrome, hepatic encephalopathy, diabetic ketoacidosis, uremia), drug and environmental toxins, hypoxic ischemic encephalopathy (HIE), inborn errors of metabolism and autoimmune causes.

APPROACH TO A CHILD WITH COMA

Any alteration in consciousness must be regarded as life-threatening emergency and urgent steps must be taken to prevent permanent brain damage. The evaluation (both clinical and laboratory) and treatment must go simultaneously throughout the acute stage. Serial evaluations with documentation are often required to determine the change in state of the child and to initiate or modify the treatment.

Emergency Management and Stabilization

As in any critical child, the treatment should begin with rapid assessment and stabilization of airway and breathing. The threshold for intubation should be low in comatose patients and if the initial GCS is less than 8 or airway is not maintainable, child should be intubated and mechanically ventilated. Stabilization

of cervical spine is of utmost importance at this point in cases of proven or suspected trauma. PaO_2 should be maintained around 100 mm Hg and $PaCO_2$ around 35 mm Hg.

Vascular access should be quickly established and necessary samples are taken. Hemodynamic instability should be treated. Hypotension should be treated by fluid resuscitation and vasoactive drugs and maintain mean arterial pressure (MAP) in normal range to maintain cerebral perfusion pressure (CPP) at age-appropriate levels. If glucose is less than 60 mg/dL, glucose should be administered as 25% dextrose (2–4 mL/kg) or 10% dextrose (5–10 mL/kg). Ongoing seizures should be treated with benzodiazepines (lorazepam 0.05–0.1 mg/kg) followed by phenytoin or fosphenytoin loading (18–20 mg/kg of phenytoin equivalents).

If there is any evidence of brain herniation or shift, emergent management of raised intracranial pressure (ICP) should be done (sedation, intubation, mild hyperventilation, raising head end to 30 degrees, keeping head in midline and give mannitol or hypertonic saline). Toxidromes should be considered in unexplained coma and administer specific antidotes if indicated.

History

A careful history should be taken with special emphasis on the events leading to onset of coma. Sudden onset of coma in a previously healthy child may be due to trauma (accidental or non-accidental), seizure, poisoning or hemorrhagic or ischemic stroke. Fever suggests an infective cause but may also indicate intracranial hemorrhage, anticholinergic poisoning or heat stroke. Failure to thrive and neurodevelopmental dysfunction before onset of coma, family history, parental consanguinity and recurrent encephalopathy may suggest inborn errors of metabolism. The chief features to be evaluated in history are summarized in **Table 1**.

General Physical Examination

The examination should begin with assessment of vital signs **(Table 2)**. Presence of jaundice is indicative of liver dysfunction. Skin examination gives important clues about trauma (bruises, lacerations), hepatic dysfunction (jaundice, spider nevi), hematological cause (petechiae) or infection (petechiae and purpura in meningococcemia). Hepatomegaly and/or splenomegaly point towards metabolic, hematological or hepatic dysfunction. Examination of head (anterior fontanel, sutures, head circumference, Macewen sign) and spine (dorsal dermal sinus, signs of occult dysraphism) may provide important diagnostic clues.

Neurological Examination

The purpose of neurological examination in comatose child is to assess depth of coma, recognize focal signs and to assess brainstem dysfunction. The key elements of examination providing vital information regarding depth of coma and localization are—level of consciousness, respiratory pattern, brainstem responses (pupillary, corneal reflex, extraocular movements) and motor response of limbs.

Level of Consciousness

The level of consciousness must be assessed at the outset before any sedatives or neuromuscular blockade. After observing the child for spontaneous motor activity, the motor response should be tested by providing adequate stimuli of graded intensity, starting with verbal commands, vigorous shaking and then painful stimuli (at nail bed, temporomandibular joint and supraorbital notch). The stimulus should be tested on both the sides to look for any asymmetry and localization to pain requires the patient's contralateral arm to cross the midline towards the noxious stimulus. Various coma scales

Table 1 History in comatose child

Events leading to onset	Sudden onset suggests trauma, seizure, stroke or poisoning
Fever, headache, vomiting	Intracranial infection (meningitis/encephalitis)
Seizures at onset	Convulsive or nonconvulsive status epilepticus, poisoning (carbon monoxide, organophosphates, camphor, etc.)
Drug or toxin exposure	Enquire for presence of any drugs at home
History of trauma	Also rule out nonaccidental trauma
History of dog bite	Rabies encephalitis
Recent immunizations	ADEM
Recurrent episodes of encephalopathy	IEM, recurrent toxin exposure
Other concurrent systemic illness	For example, jaundice (hepatic failure), pneumonia (hypoxic encephalopathy), diarrhea (dyselectrolytemia), dysentery (*Shigella* encephalopathy)
Past medical illness	Diabetes mellitus, congenital heart disease, renal failure, liver disease
Family history of previous infant/child deaths	IEM, SIDS
Residence of child	Endemic for cerebral malaria, any epidemic of viral encephalitis in neighborhood

Table 2 General physical examination in comatose child

Fever	Sepsis, focal infective process (meningitis, brain abscess), subarachnoid hemorrhage, pontine hemorrhage, heat stroke, drugs (cholinergic drugs)
Hypothermia	Sepsis, drugs intoxication (sedative/hypnotic or opioid), hypoglycemia, adrenal crisis
Tachycardia	Fever, hypovolemic or septic shock, heart failure or arrhythmias, adrenergic response to acute brain insult, intoxications (tricyclic antidepressants)
Bradycardia	Raised ICP, myocardial injury, intoxications (beta blockers, organophosphates)
Hypertension	Hypertensive encephalopathy, compensatory mechanism to CPP in children with raised ICP
Hypotension	Sepsis, cardiac dysfunction, toxic ingestion, or adrenal insufficiency
Pallor	Cerebral malaria, intracranial bleed, hemolytic uremic syndrome
Jaundice	Hepatic encephalopathy, complicated malaria
Rashes	Meningococcemia, dengue, measles, rickettsial diseases
Petechiae	Dengue, DIC with streptococcal, staphylococcal or meningococcal species or Rickettsia
Head and scalp	*Hematoma:* Traumatic/non-accidental injury; dilated veins, full AF, sutural separation, Macewen sign—hydrocephalus
Spine	Dorsal dermal sinus, tuft of hair (occult spinal dysraphism)

Abbreviations: ICP, intracranial pressure; CPP, cerebral perfusion pressure; DIC, disseminated intravascular coagulation; AF, anterior fontanel.

include essential elements of neurological examination. Most commonly used scale is that developed by Teasdale and Jennett—Glasgow Coma Scale (GCS). The GCS works well for patients aged 5 years and above **(Table 3)**, but below that age, modifications, particularly of the verbal scale, are needed. There have been some limitations in use of GCS. A simple scale, AVPU (alert, response to voice, response to pain, unresponsive) is about as accurate as the GCS and much easier to use. However, no scale is adequate for all patients; hence, the best policy in recording the results of the coma examination is simply to describe the findings.

Respiratory Pattern

After securing airway, one should observe the breathing pattern **(Table 4)**. Respiratory rhythm is generated by a network of neurons that lie in the ventrolateral medulla. The pattern of respiration can give important clues concerning the level of brain damage but are not of much localization value as most of these patterns also occur in metabolic encephalopathies.

Brainstem Reflexes

The important brainstem reflexes of localization value are pupillary response, corneal reflex, oculocephalic reflex, vestibulo-ocular reflex (cold caloric testing) and, gag and cough reflexes. The pupillary light reflex is very resistant to metabolic dysfunction

Table 3 Glasgow coma scale with modification for children and intubated patients

Best eye response			
1	No eye opening		
2	Eye opening to pain		
3	Eye opening to verbal command		
4	Eyes open spontaneously		

Best verbal response			
	Adult version (> 5 years)	Children's modification	Grimace response for preverbal or intubated patients
1	No verbal response	No vocal response	No response to pain
2	Incomprehensible sounds	Occasionally whimpers and/or moans	Mild grimace to pain
3	Inappropriate words	Cries inappropriately	Vigorous grimace to pain
4	Confused	Less than usual ability and/or spontaneous irritable cry	Less than usual spontaneous ability or only response to touch stimuli
5	Oriented	Alert, babbles, coos, words or sentences to usual ability	Spontaneous normal facial/oromotor activity

Best motor response	
1	No motor response to pain
2	Abnormal extension to pain
3	Abnormal flexion to pain
4	Withdrawal to painful stimuli
5	Localizes to painful stimuli or withdraws to touch
6	Obeys commands or performs normal spontaneous movements

Table 4 Respiratory patterns and their localizing value in comatose patient

Type of breathing pattern	Localization/etiology
Cheyne-Stokes respiration: hyperpnea alternating regularly with apnea	Metabolic encephalopathies (hepatic failure, uremia), forebrain or diencephalic dysfunction function (intact brainstem respiratory reflexes)
Central neurogenic hyperventilation	Metabolic encephalopathies, midbrain and pontine lesions
Apneustic breathing—inspiratory pauses	Bilateral pontine lesions (basilar artery infarcts), rarely in metabolic encephalopathies like hypoglycemia, anoxia or meningitis
Ataxic or irregular, gasping respiration	Lower pontine and medullary lesions
Apnea	Ventrolateral medullary reticular formation

and is very important in differentiating metabolic from structural coma. Asymmetric pupils are caused either by disruption of the oculomotor nerve (cranial nerve III) or impairment of sympathetic fibers (Horner syndrome). Topical administration of mydriatics must be ruled out. Pupillary size, shape, symmetry and response to light provide valuable clues to brainstem and third nerve dysfunction **(Table 5)**. The presence of anisocoria in the comatose patient should be as considered evidence of ipsilateral uncal herniation caused by structural lesion unless proved otherwise.

The presence of oculocephalic (doll's eye), oculovestibular, corneal, cough and gag reflexes are indicative of intact brainstem function. Normal response (smooth conjugate movement of eyes opposite to movement of head) to oculocephalic reflex indicate intact brainstem pathway from vestibular nuclei through pontine and midbrain tegmentum. In a comatose child, slow conjugate movement of the eye towards the stimulated side indicates an intact brainstem (vestibular nuclei in medulla to oculomotor nuclei in midbrain and pons connected by medial longitudinal fasciculus). This response should not be confused with direction of nystagmus (fast component opposite to side of cold water; the traditional *COWS* pneumonic) in awake patient. Comatose patients will not have nystagmus (rapid component away from the side of irrigation) and nystagmus indicates intact cortical function (as seen with psychogenic coma).

Eye movements and position are informative but have less localizing value. Spontaneous roving eye movements indicate that the brainstem is intact, whereas skew deviation (vertical misalignment of the eyes) suggests a brainstem lesion. Conjugate gaze deviation to one side generally indicates an ipsilateral hemispheric or contralateral pontine lesion (parapontine reticular formation) or contralateral hemispheric seizure focus.

Table 5 Pupillary responses at different levels of the brain lesions

Anatomical site involved	Pupils size and reaction
Diencephalic, metabolic	Small, reactive
Midbrain, tectum	Midposition, unreactive, spontaneous hippus
Midbrain, tegmentum	Midposition, irregular, unreactive, corectopia (noncentered)
Third nerve or fascicular (uncal herniation)	Large, unresponsive (Unilateral)
Pons	Pinpoint, responsive

Motor Response

The trunk's and limb's position, spontaneous movements and response to stimulation must be observed to look for any focal deficits (suggestive of postictal Todd's palsy or structural abnormality). Decerebrate posturing is indicative of injury to the caudal diencephalon, midbrain or pons. Decorticate posturing suggests supratentorial lesion (hemispheric or thalamic damage), with sparing of structures below the diencephalon. Posturing often indicate brainstem herniation and should not be confused with seizures. Extrapyramidal movements (dystonia, rigidity) may be seen in Japanese B encephalitis, tubercular meningitis, inborn errors of metabolism (glutaric academia I, mitochondrial cytopathy), anti-NMDAR encephalitis and metoclopramide toxicity.

The fundi must always be examined to look for retinal hemorrhages and papilledema. Retinal hemorrhages strongly suggest intracranial hemorrhage and the possibility of child abuse must be considered. Papilledema may be seen early in the comatose state but is rare. Raised ICP is unlikely in the presence of venous pulsations. The absence of venous pulsation is not helpful. Signs of meningeal irritation may be present in meningitis, encephalitis and subarachnoid hemorrhage. Neck rigidity is present in meningitis, tonsillar herniation or craniocervical trauma. The Kernig and Brudzinski signs are more reliable signs of meningeal irritation.

INVESTIGATIONS (BOX 2)

Some investigations are basic and needs to be done on every comatose child and others are tailored as per clues from history and examination.

Neuroimaging

A *cranial CT* is often the first line neuroimaging and should be performed if focal signs are present or raised ICP is suspected. The value of CT in detecting mass lesions, hemorrhage, skull fractures and hydrocephalus is well established. Obliteration of basal cisterns and midline shift on CT are indicative of raised ICP. A contrast study may reveal features of infection in the form of meningeal enhancement, brain abscess or neurocysticercosis. Certain pathologies like early infarcts, encephalitis and posterior fossa structures may be difficult to visualize. Raised ICP is suggested by effacement of sulci, chinked ventricles and effacement of cisterns. In cases with no history of acute trauma, MRI brain is the preferred modality. MRI is superior to CT for the detection of acute ischemic stroke, encephalitis, demyelination in acute disseminated encephalomyelitis (ADEM), traumatic diffuse axonal injury and posterior fossa lesions.

EEG

It is essential in diagnosing nonconvulsive status epilepticus. Continuous EEG monitoring is mandatory under the following situations: refractory seizures; and patients who are heavily sedated, receiving neuromuscular blocking agents, or being treated with barbiturates for increased ICP.

Other Investigations

In cases of unexplained or recurrent encephalopathy, *work-up for inborn error of metabolism (IEM)* must be done, which include blood ammonia, serum and cerebrospinal fluid (CSF) lactate, urine ketones, plasma amino acids and acylcarnitine profile and urine for organic acids. If a specific history is not obtained, and the cause of coma is not apparent (especially in a teenager or toddler) on above investigations, *a toxicology screen* should be done.

Other investigations in unexplained coma include thyroid function tests and *thyroid antibodies* (for Hashimoto encephalopathy) and work-up for central nervous system vasculitis. If there are associated psychiatric manifestations with extrapyramidal features along with seizures, and frequent autonomic instability, *anti-NMDA receptor antibodies* must be done in serum and CSF.

TREATMENT

Management of a child with coma usually proceeds simultaneously with the clinical evaluation. The emergency treatment and stabilization has already been discussed above and treatment of raised ICP and status epilepticus are discussed in appropriate sections. Specific treatment should be directed to suspected underlying etiology.

- In case of acute febrile encephalopathy, broad spectrum antibiotics (ceftriaxone) should be instituted immediately. If viral encephalitis is likely, then samples for polymerase chain reaction (PCR) for herpes simplex virus should be sent and acyclovir should be started. Antimalarials should be started if there is a clinical suspicion of cerebral malaria.
- *Antidotes:* Naloxone should be used in case of suspected opiate poisoning. Flumazenil is useful for benzodiazepine overdosage.
- Steroids are of benefit in ADEM, meningococcemia with shock, enteric encephalopathy, autoimmune encephalitis (anti-NMDAR encephalitis), tubercular meningitis and pyogenic meningitis.
- If metabolic causes are identified, e.g., diabetic ketoacidosis, hepatic encephalopathy, uremia or hyperammonemia, these should be treated appropriately.

BOX 2 Laboratory tests in comatose child

Initial lab tests
- Blood Glucose
- Electrolytes (Na, K, Cl, Ca)
- Arterial blood gas
- Complete blood counts
- Urea and creatinine
- Liver function tests
- RDT for malaria in endemic area
- Blood culture (in febrile encephalopathy)
- CSF (If meningitis is suspected and there is no contraindication):
  – Cell count, Gram stain
  – Protein, Sugar
  – Cultures

Second tier tests
- *Ammonia levels:* Raised in urea cycle disorders, valproate toxicity and hepatic failure
- *IEM screen:* Serum and CSF lactate, urine ketones, plasma amino acids and acylcarnitine profile (TMS) and urine for organic acids (GCMS)
- Toxicology screen
- Anti-NMDA receptor antibodies (especially if psychiatric features and extrapyramidal features)
- Anti-TPO antibodies (for suspected Hashimoto encephalopathy)
- Autoimmune work-up

RAISED INTRACRANIAL PRESSURE

Intracranial pressure is the total pressure exerted by the brain, blood and CSF in the intracranial vault. The Monroe-Kellie hypothesis states that the rigid covering surrounding the brain creates a protected cavity and the volume contained inside remain constant, that is, the sum of the intracranial volumes of brain, blood, and CSF is constant, and that an increase in volume of one component occurs at the expense of other two.

The ICP values vary with age and normal values for ICP in children are not well established. Normal values are 1.5–6 mm Hg for term infants, 3–7 mm Hg for young children and less than 10–15 mm Hg for adults and older children. A sustained ICP value greater than 20 mm Hg is considered clearly abnormal. Values greater than 40 mm Hg indicate severe, life-threatening intracranial hypertension.

CEREBRAL PERFUSION PRESSURE

Cerebral perfusion pressure is the difference between mean arterial pressure (MAP) and ICP (CPP = MAP – ICP). It defines the pressure gradient driving cerebral blood flow (CBF). Increased ICP reduces CBF. Thus, preventing brain ischemia by controlling ICP is of paramount importance. Under normal circumstances, the brain is able to maintain a relatively constant CBF over a wide range of CPP (60–150 mm Hg in adults) by the process of autoregulation. This process is compromised in patients with raised ICP and the CBF becomes pressure passive wherein systemic hypotension can lead to additional ischemic injury. The pediatric guidelines for severe traumatic brain injury (TBI) suggest that CPP more than 40 mm Hg should be maintained and CPP between 40 mm Hg and 65 mm Hg probably represents an age related continuum for the optimal treatment threshold. Recent data in severe pediatric TBI defined age specific threshold for CPP and suggest that CPP goals of 50–60 mm Hg in adults, more than 50 mm Hg in 6–17 years old, and more than 40 mm Hg in 0–5 years old appear to be appropriate targets for treatment-based studies.

HERNIATION SYNDROMES

As ICP increases within the rigid skull, the capacity of vascular and CSF spaces to compensate get exceeded and there is displacement of brain tissue from one compartment to other. An immediate priority is to look for potentially life threatening signs of herniation **(Table 6)**. One needs to carefully look for subtle sensorial changes, respiratory abnormalities and pupillary change. If these signs are present then measures to decrease ICP should be rapidly instituted. Cushing's triad (bradycardia, hypertension and irregular breathing) is a late sign of herniation.

INTRACRANIAL PRESSURE MONITORING

Indications

The association between raised ICP and poor outcome in TBI has been confirmed in various pediatric and adult studies. However, there is still debate regarding usefulness of ICP monitoring in traumatic and nontraumatic coma mainly because of lack of any randomized controlled trials. ICP monitoring is indicted for a patient with GCS score of 3–8 (after resuscitation) with either an abnormal admission head CT or motor posturing and hypotension. Evidence based reviews on use of ICP monitoring in severe traumatic brain injury in children provides strong support for its use. It is been found beneficial for the outcome and in determining a treatment threshold. The role and benefit of ICP monitoring remains unclear in other conditions such as subarachnoid hemorrhage, hydrocephalus, stroke, intracranial infections, and Reye's syndrome. In other brain injuries, such as hypoxic and ischemic injuries, monitoring ICP has not been shown to improve outcome.

Intracranial Pressure Monitoring Devices

The most common methods used for ICP monitoring are intraventricular and intraparenchymal catheters. The gold standard for ICP monitoring is intraventricular catheter or ventriculostomy drain. The ventricular catheter is connected to standard pressure transducer. The reference point for ICP monitor is foramen of Monro, although practically, the external auditory meatus is used as a landmark. The advantages of ventriculostomy catheters are ability to perform external calibration and therapeutic CSF drainage. The disadvantages are difficulty in placement when ventricles are effaced (which is a common scenario in raised ICP) and higher rate of infection than intraparenchymal catheters. The intraparenchymal catheters are easy to insert and have lower risk of infections but the main disadvantage is that it cannot be calibrated in vivo and may show zero drift over time.

Intracranial Pressure Waveforms

Normal ICP waveform consist of three arterial components—percussion wave (reflects the ejection of blood from heart

Table 6 Clinical recognition of herniation syndromes

Type of herniation	Mechanism	Clinical manifestations
Subfalcine or cingulate herniation	Displacement of the brain (typically the cingulate gyrus) beneath the free edge of the falx cerebri	Impaired consciousness, contralateral leg weakness (due to compression of ACA)
Central transtentorial	Downward displacement of both cerebral hemispheres and diencephalon through tentorial notch causing brainstem compression	*Diencephalic stage*: *Symmetrical small reactive pupils, decorticate* posturing, preserved oculocephalic and oculovestibular reflexes, Cheyne-Stokes breathing *Midbrain-upper pons stage:* Midposition unreactive pupils, decerebrate posturing, absent oculocephalic and oculovestibular reflexes, hyperventilation *Lower pons-medullary stage:* Absent spontaneous motor movements (lower extremities may withdraw to plantar stimulation), midposition fixed pupils, ataxic respiration *Medullary stage:* Flaccid, absent pupillary reflexes and ocular movements, irregular or gasping respiration
Lateral transtentorial (Uncal herniation)	Displacement of uncus of temporal lobe over the free edge of tentorium	Impaired consciousness, abnormal respirations, *ipsilateral third nerve palsy* (unilateral dilated pupil, ptosis), ipsilateral *hemiparesis (compression of contralateral cerebral peduncle—Kernohan notch)*
Tonsillar herniation	Increased pressure in posterior fossa causing brainstem compression and downward of cerebellar tonsils and medulla	Impaired consciousness, neck rigidity, opisthotonus, irregular respirations, apnea and bradycardia

Abbreviation: ACA, anterior cerebral artery.

and transmitted to choroid plexus), tidal wave (reflects brain compliance) and dicrotic wave (which reflects aortic valve closure). Under normal conditions, percussion wave is tallest and tidal and dicrotic waves are of decreasing amplitude. When there is raised ICP, cerebral compliance is diminished, which is reflected in increase in peak of tidal and dicrotic waves exceeding that of percussion wave.

MANAGEMENT OF RAISED INTRACRANIAL PRESSURE (FLOW CHART 1)

When elevated ICP is clinically evident, the situation is urgent and requires immediate reduction in ICP. The availability of ICP monitors is not universal and should not come in the way of emergent therapy. When facilities for ICP monitoring are available the management is tailored to:

- Maintaining an adequate CPP (> 50 mm Hg in 6–17 years old, and > 40 mm Hg in 0–5 years old)
- Lower ICP to acceptable levels (< 20 mm Hg for children older than 8 years, < 18 for 1–8 years, and < 15 mm Hg for infants). Several medical and surgical options are available to reduce ICP. A stepwise approach is usually followed with the least toxic therapies utilized first and then second tier and more toxic therapies are added if first tier therapies are unsuccessful.

Respiratory Management

The threshold for intubation should be low in a child with altered consciousness. Early intubation should be considered for those children with GCS less than 8, evidence of herniation, apnea or have inability to maintain airway. Intubation should be carried out by trained personnel and should be preceded by adequate sedation and short acting neuromuscular blockade.

Sedation and Analgesia

After intubation and volume resuscitation (managing ABC), sedation, analgesia and neuromuscular blockade are first steps to control ICP. Benzodiazepines (midazolam infusion) and narcotics (morphine or fentanyl) are used for this purpose. Adequate analgesia and sedation is usually preferred over neuromuscular blockade, as it is quickly reversible and allows for neurological monitoring. If sedatives are not completely effective, then a neuromuscular blocking agent (e.g., pancuronium, atracurium, vecuronium) may be required. However, continuous EEG monitoring and ICP monitoring is recommended with the use of neuromuscular blockers.

Position

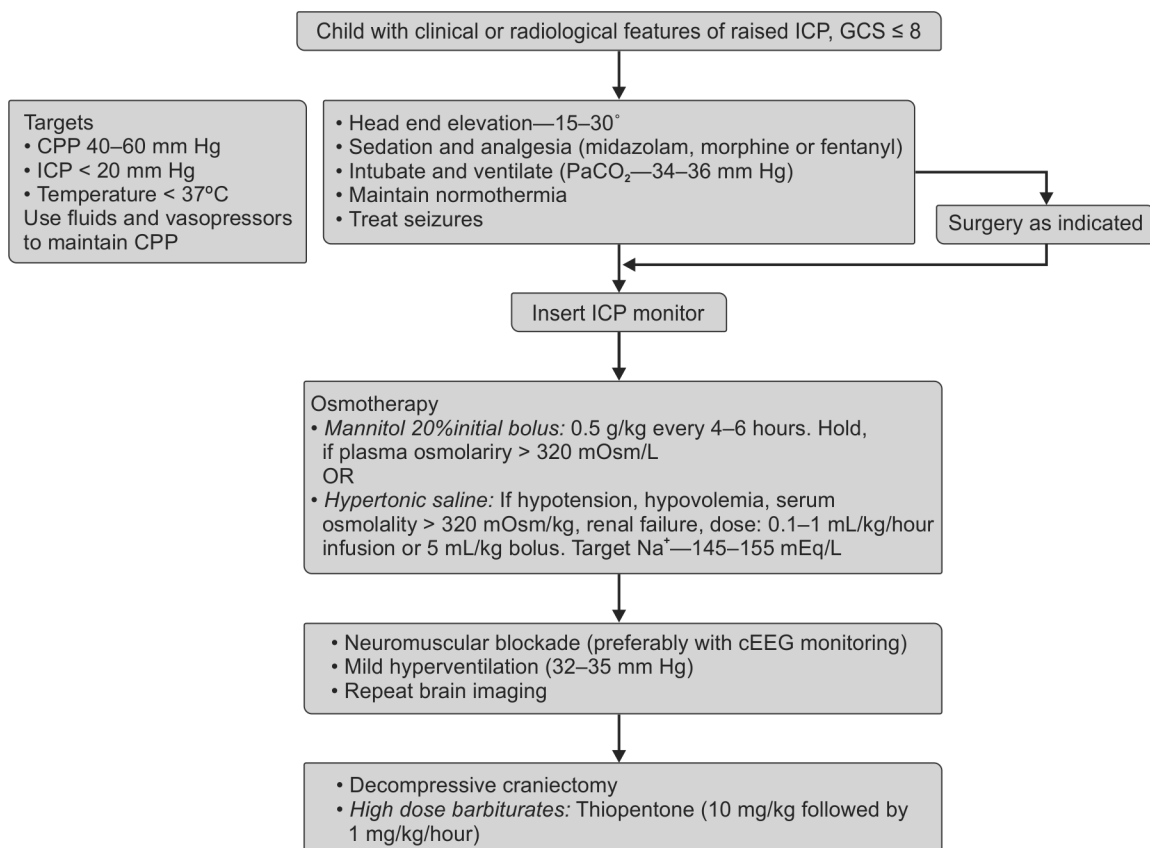
The other first tier therapy is mild head elevation of 15–30˚. The child's head is positioned midline with the head end of the bed elevated to 15–30˚ to encourage jugular venous drainage. One has to ensure that the child is euvolemic prior to placing in this position.

Fluid Management

Normovolemia should be maintained by fluid resuscitation with isotonic saline if needed. Hypotonic solutions should not be used. In CPP directed therapy, vasopressors are used to increase MAP so as to maintain CPP as per set goals.

Osmotherapy

If ICP is still elevated, mannitol or hypertonic saline can be started. Mannitol is an osmotic diuretic and also decreases blood viscosity and hematocrit and increases CBF and cerebral oxygen delivery. Use an initial bolus of 0.25–1 g/kg (the higher dose for more urgent reduction of ICP) followed by 0.25–0.5 g/kg boluses repeated every

Flow chart 1 Treatment of raised intracranial pressure


2–6 hours as per requirement. Its duration of effect is 3–5 hours. Hypertonic saline has a clear advantage over mannitol in children who are hypovolemic or hypotensive. Other situations where it may be preferred are renal failure or serum osmolality greater than 320 mOsmol/kg. It has been found effective in patients with serum osmolality of up to 360 mOsmol/kg. It would be reasonable to administer hypertonic saline as a continuous infusion at 0.1–1.0 mL/kg/hour to target a serum sodium level of 145–155 mEq/L.

Hyperventilation

If despite these measures the ICP remains above 20 mm Hg, the ventilator rate can be adjusted to keep PCO_2 30–35 mm Hg. Hyperventilation acts by constriction of cerebral blood vessels and lowering of CBF. However, studies in children with traumatic brain injury have demonstrated aggressive hyperventilation dramatically decreases the CBF, causing or aggravating cerebral ischemia. This often results in poorer outcome in these patients. The most effective use of hyperventilation is for acute, sharp increases in ICP or signs of impending herniation.

Decompressive Craniectomy

This may be considered if above measures fail to control ICP in salvageable patients. Pediatric guidelines of severe TBI suggest the use of decompressive craniectomy as an option in the treatment of medically refractory intracranial hypertension was recommended. The recommendation noted that children with a potentially recoverable brain injury and those who experience secondary deterioration within 48 hours after injury may be more likely to benefit from surgery and that children with severe secondary injury at the time of presentation may be less likely to benefit.

Barbiturate Coma

Pentobarbital can be used to induce burst suppression and control ICP by reducing metabolic activity. A commonly used protocol is to use loading dose of 10 mg/kg over 30 min followed by 1 mg/kg/hour. The complication rate of barbiturate therapy is high and includes hypotension, hypokalemia, respiratory complications, infections, hepatic dysfunction and renal dysfunction.

Hypothermia

Evidence from carefully conducted studies in adults and children do not show any improvement in the neurologic outcome in head injured patients with the use of therapeutic hypothermia. However, studies do suggest a lowered ICP during the hypothermia therapy in children. So in children with refractory raised ICP controlled hypothermia may be tried.

BRAIN DEATH

Brain death is the irreversible cessation of all functions of the entire brain, including the brainstem. Determination of brain death by neurological criteria is a clinical diagnosis. The guidelines for the determination of brain death in children were published by a multi-society task force in the USA in 1987. As per these guidelines, after certain prerequisites are met, the three key components of clinical brain death diagnosis are demonstrations of irreversible coma/unresponsiveness, absence of brainstem reflexes, and apnea. In addition, age-related observation periods and the need for specific ancillary tests were recommended for all children younger than 1 year of age. These guidelines were extensively updated and revised in 2011 **(Table 7)**.

Determination of brain death in neonates, infants and children relies on a clinical diagnosis that is based on the absence of neurologic function with a known irreversible cause of coma. Coma and apnea must coexist to diagnose brain death. This diagnosis should be made by physicians who have evaluated the history and completed the neurologic examinations.

Prerequisites for Initiating Clinical Brain Death Evaluation

Factors potentially influencing the neurologic examination such as dyselectrolytemia, shock and hypothermia (maintain core body temperature > 35°C) must be corrected prior to examination. All sedation, neuromuscular blockers and anticonvulsants must be discontinued for a reasonable time period (based on elimination $t_{1/2}$). The neurological evaluation should be deferred for 24–48 hours after cardiopulmonary resuscitation.

Number of Examinations and Observation Period

Two examinations including apnea testing with each examination separated by an observation period are required. The examinations should be performed by different attending physicians involved in the care of the child. The recommended observation periods are 24 hours for neonates (37 weeks' gestation to term infants 30 days of age) and 12 hours for infants and children (> 30 days to 18 years).

Table 7 Neurological examination components to assess brain death

• *Coma*: Complete loss of consciousness, vocalization, volitional activity, eye opening or eye movements	Noxious stimuli should not produce a motor response other than spinally mediated reflexes
• *Loss of all brainstem reflexes including*	
Midposition or fully dilated pupils which do not respond to light	Usually the pupils are fixed in a midsize or dilated position (4–9 mm)
Absence of movement of bulbar musculature including facial and oropharyngeal muscles	Deep pressure on the condyles at the level of the temporomandibular joints supraorbital ridge should produce no grimacing or facial muscle movement
Absent gag, cough, sucking, and rooting reflex	Tested by stimulating posterior pharynx with a tongue blade and by examining the cough response to tracheal suctioning
Absent corneal reflexes	Absence of eyelid movement by touching the cornea with a piece of tissue paper, a cotton swab, or squirts of water
Absent oculovestibular reflexes	The oculovestibular reflex is tested by irrigating each ear with ice water (caloric testing)
• Apnea testing	
• Flaccid tone and absence of spontaneous or induced movements, excluding spinal cord events such as reflex withdrawal or spinal myoclonus	Observe the patient for any spontaneous or induced movements. If abnormal movements are present, clinical assessment to determine whether or not these are spinal cord reflexes should be done

Apnea Testing

The patient must have the complete absence of documented respiratory effort (if feasible) by formal apnea testing demonstrating a $PaCO_2$ greater than or equal to 60 mm Hg and greater than or equal to 20 mm Hg increase above baseline. The patient should be preoxygenated using 100% oxygen for 5–10 minutes prior to initiating this test. Mechanical ventilation should be discontinued once the patient is well oxygenated and a normal $PaCO_2$ has been achieved. Follow-up blood gases should be obtained to monitor the rise in $PaCO_2$ while the patient remains disconnected from mechanical ventilation. If no respiratory effort is observed from the initiation of the apnea test to the time the measured $PaCO_2$ greater than or equal to 60 mm Hg and greater than or equal to 20 mm Hg above the baseline level, the apnea test is consistent with brain death. Apnea test should be terminated if oxygen saturations fall below 85% or there is hemodynamic instability.

Ancillary Studies

Ancillary studies (EEG and radionuclide cerebral blood flow) are not required to establish brain death unless the clinical examination or apnea test cannot be completed. These are required:

- To reduce the observation period
- If apnea testing cannot be completed safely due to the underlying medical condition of the patient
- If there is uncertainty about the results of the neurological examination
- If a medication effect may interfere with evaluation of the patient.

If the ancillary study is equivocal or if there is concern about the validity of the ancillary study, the patient cannot be pronounced dead. The patient should continue to be observed until brain death can be declared on clinical examination criteria and apnea testing, or a follow-up ancillary study can be performed to assist with the determination of brain death. A waiting period of 24 hours is recommended before further clinical reevaluation or repeat ancillary study is performed. Supportive patient care should continue during this time period.

Declaration of Brain Death

Brain death is declared after the second neurologic examination and apnea test confirm an unchanged and irreversible condition. When ancillary studies are used, documentation of components from the second clinical examination that can be completed, including a second apnea test, must remain consistent with brain death. All aspects of the clinical examination, including the apnea test, or ancillary studies must be appropriately documented.

IN A NUTSHELL

1. The most common etiology of coma in children are infections (encephalitis, meningitis)
2. Securing cervical spine (in suspected or proven trauma) and stabilization of airway, breathing and circulation is the first step in managing comatose child.
3. The key elements of neurological examination in a comatose child are: level of consciousness, respiratory pattern, brainstem responses (pupillary, corneal reflex, extraocular movements) and motor response.
4. It is important to recognize herniation syndromes and institute immediate therapy to reduce intracranial hypertension.
5. ICP monitoring (intraventricular or parenchymal) helps to decide treatment threshold in comatose child. Its role in traumatic brain injury is well established.
6. The goals of managing raised ICP are to maintain CPP 40–60 mm Hg and keep ICP less than 20 mm Hg.
7. The first tier treatments in raised ICP include intubation, sedation and analgesia, neuromuscular blockade, osmo-therapy and mild hyperventilation.
8. Second tier therapies include aggressive hyperventilation, decompressive craniectomy, barbiturate coma and therapeutic hypothermia.
9. The three key components of clinical brain death diagnosis are demonstrations of irreversible coma/unresponsiveness, absence of brainstem reflexes, and absence of documented respiratory effort by formal apnea test.

Chapter 42.14
Stroke
Ramesh Konanki

Stroke is defined by the World Health Organization (WHO) as *a clinical syndrome of rapidly developing focal or global disturbance of brain function lasting more than 24 hours or leading to death with no obvious nonvascular cause*. The duration cut-off of 24 hours is in the context of defining another vascular event, i.e., transient ischemic attack (TIA) as *a sudden, focal neurologic deficit that lasts for less than 24 hours, of presumed vascular origin, confined to an area of the brain or eye perfused by a specific artery*. More recently the time cut-off has been restricted to less than 1 hour. But, a more pathophysiologically distinctive definition encompasses tissue criteria, i.e., presence or absence of tissue infarction to differentiate stroke (with tissue infarction) vs TIA (no tissue infarction).

Stroke is broadly classified into two types based on primary pathophysiology of disease: *ischemic stroke* due to interruption of blood flow to a part of brain, and *hemorrhagic stroke* due to rupture of blood vessels with bleeding into the cerebral parenchyma. About 55% of pediatric strokes are ischemic in nature and 45% are hemorrhagic strokes. This is in contrast to stroke in adults where 80–85% of the strokes are ischemic and 15–20% hemorrhagic. The ischemic stroke may further be classified into *arterial ischemic stroke* (AIS) due to occlusion of arteries, and *cerebral venous sinus thrombosis* (CVST) resulting from occlusion of venous sinuses **(Figs 1 and 2)**. The objective of this chapter is to highlight the salient features of childhood stroke in terms of classification, etiopathogenesis, clinical presentation and management including optimal evaluation.

ARTERIAL ISCHEMIC STROKE

Epidemiology
The term *childhood stroke* refers to stroke in children aged between 1 month and 18 years. It is not uncommon, with incidence varying depending on the age and geographic location. The reported incidence ranges from 1.2 cases per 100,000 children to 13 cases per 100,000 children (< 18 years of age). The data from International pediatric stroke study shows significant male predominance for childhood ischemic stroke regardless of age or stroke subtype. The age distribution of stroke is highly variable during childhood, disproportionately affecting infants (2.5 per 100,000 children per year) especially those with congenital heart disease and perinatal asphyxia. The stroke incidence decreases to nearly half (1.25 cases per 100,000 children per year) if infants are excluded from the study population. There is no population based data regarding true burden of childhood stroke in India. As per hospital based studies, childhood stroke (1–16 years of age) constitute 5–15% of all strokes in the young (< 40 years) and 0.7% of all pediatric admissions.

Recurrence is estimated to occur in 20% of children with stroke. However, risk factors predicting the recurrence are poorly understood. Stroke recurrence is thought to be more prevalent if multiple risk factors are present.

Etiology
Identification of an etiology in childhood stroke is challenging because of diverse risk factor profile **(Box 1)**. The predominant causes for ischemic stroke in children can be grouped into (1) structural heart disease, (2) vasculopathies (inflammatory and noninflammatory), (3) hematological disorders, and (4) prothrombotic states (inherited and acquired). The prevalence of risk factors varies depending on the geographic location. For example, moyamoya disease is one of the most common causes in Japan, where as sickle cell disease is an important cause in regions with high prevalence of this disease.

Structural Heart Disease and Thromboembolism
Cardiac causes of stroke are more prevalent in younger children (up to 2 years of age). Congenital heart disease, rheumatic heart disease, infective endocarditis and cardiomyopathy are the major cardiac causes of stroke with thromboembolism being the main pathophysiological mechanism. Embolic stroke is an important complication of cardiac surgery during intraoperative and immediate postoperative periods (e.g., Fontan operation).

Another important group of conditions with thromboembolic stroke include trauma to carotid vessels in the neck or throat (anterior circulation stroke), and vertebral artery dissection associated with craniovertebral junction anomalies (posterior circulation stroke).

(C) MR venogram showing occlusion of the left transverse and sigmoid sinuses (arrowheads)

BOX 1 Etiology of ischemic stroke in children

Structural heart disease and thromboembolism
- Congenital heart disease
- Rheumatic heart disease, infective endocarditis
- Cardiomyopathies, arrhythmias
- Prosthetic, prolapsed valves
- Cardiac interventions (e.g., Fontan operation)
- Neck trauma, and craniovertabral junction anomalies

Vasculopathies
- *Infective vasculitis:* Pyogenic, fungal, tuberculous, AIDS, mycoplasma
- *Noninfective vasculitis:* SLE, polyarteritis nodosa, Takayasu arteritis
- Post varicella angiopathy
- *Noninflammatory vasculopathies:* Moyamoya disease, migraine, Marfan syndrome, Ehlers-Danlos syndrome, fibromuscuar dysplasia

Hematological causes
- *Hemoglobinopathies:* Sickle cell anemia
- Thrombocytosis
- Polycythemia
- Lymphoreticular malignancies

Prothrombotic states
- Protein C, S deficiency, antithrombin III deficiency
- Activated protein C resistance, factor V leiden mutation, prothrombin mutation
- Lupus anticoagulant, aCL, IgG and IgM
- Elevated lipoprotein (a)
- Hyperhomocysteinemia and MTHFR mutation

Metabolic causes
- Homocystinuria
- MELAS and Leigh disease
- Fabry disease, Ornithine transcarbamylase deficiency, sulphite oxidase deficiency
- Organic acidemias (Methylmalonic academia, Propionic academia, Isovaleric academia, Glutaric academia type I)

Drugs
- Cocaine, amphetamine, triptans, ergots

Miscellaneous risk factors
- Iron deficiency anemia, lenticulostriate artery mineralization

Abbreviations: SLE, systemic lupus erythematosus; MTHFR, methylenetetrahydrofolate reductase; MELAS mitochondrial encephalopathy, lactic acidosis and stroke-like episodes; aCL, anticardiolipin antibody.

Hematological Causes

Sickle cell disease, thrombocytosis and polycythemia are the second most common etiologies causing ischemic stroke. Children with sickle cell disease are highly vulnerable to cerebrovascular events, with incidence of stroke being as high as 285 cases per 100,000 children. Twenty five percent of patients with sickle cell anemia develop cerebrovascular complications, of which 80% are under 15 years of age. Mean age of stroke is 7.7 years and recurrence risk is 67%.

Vasculopathies

Infective vasculitis, noninfective inflammatory vasculitis and noninflammatory vasculopathies are other major causes of ischemic stroke **(Box 1)**. Of these, moyamoya disease is highly prevalent in Japan and some East Asian countries, whereas infective vasculitides are mostly seen in developing countries with high rates of central nervous system infections **(Figs 3A to C)**. Moyamoya disease is a vasculopathy with progressive stenosis of supraclinoid portion of internal carotid arteries, with development of extensive collaterals from other vascular territories. The appearance of these collaterals on angiogram is given the name *puff of smoke* **(Figs 4 and 6)**. *Moyamoya disease* is a cerebrovascular disorder of unknown etiology characterized by progressive occlusion of supraclinoid internal carotid arteries and variable occlusion of its branches. When the similar clinical and radiological features are seen in association with conditions including Down syndrome, neurofibromatosis, autoimmune disease, cerebrovascular atherosclerosis, cranial irradiation or cerebral neoplasm, it is called *moyamoya syndrome.* Another important childhood vasculopathy is post-varicella angiopathy (PVA). Stroke can be seen in children after varicella infection with latency period ranging from 2–4 weeks to 12 months. It is more frequently seen in anterior circulation, and the diagnosis is confirmed by corroborative evidence of positive varicella zoster specific antibodies in cerebrospinal fluid.

Prothrombotic States

Prothrombotic states (inherited and acquired) account for 20–50% of children with AIS and 33–99% of children with CVST. Of these, factor V Leiden, hyperhomocysteinemia and methylenetetrahydrofolate reductase (MTHFR) polymorphisms, protein C deficiency, and anticardiolipin antibodies are the most
Figures 3A to C Tubercular meningitis with vasculitic infarcts. (A) Axial FLAIR and (B) T2 weighted images of the brain showing nonterritorial infarcts along the margins of the sylvian fissures on either side. (C) Axial postcontrast T1 weighted image shows enhancing exudates within the sylvian fissure (arrowheads)
Figures 4A to C Moyamoya disease. (A) Axial diffusion weighted and (B) T2 weighted images of the brain showing subacute infarcts in the distribution of the right middle cerebral and bilateral anterior cerebral arteries. (C) MR angiogram shows critical stenosis involving the terminal segments of both internal carotid arteries (arrowheads)

common inherited prothrombotic states. Acquired prothrombotic states include chronic liver disease and protein-losing states like nephrotic syndrome. The data from hospital-based studies has shown hyperhomocysteinemia, MTHFR polymorphism, protein C and S deficiency and antiphospholipid antibodies as the most common prothrombotic states among Indian children with ischemic stroke.

Metabolic Causes

Homocystinuria, mitochondrial encephalomyopathy with lactic acidosis and strokelike episodes (MELAS), Leigh disease, familial hyperlipidemias, Fabry disease and organic acidemias (methylmalonic aciduria, propionic acidemias, isovaleric acidemias, glutaric acidemia type I) are some of the rare causes of ischemic stroke.

Miscellaneous Risk Factors

Focal cerebral arteriopathy is another vasculopathy affecting lateral lenticulostriate arteries due to vessel wall involvement of distal internal carotid artery or proximal middle or anterior cerebral arteries. It may be progressive (5–10% children) or transient (nearly 90%). Serial neuroimaging is indicated in children suspected with focal cerebral arteriopathy. *Mineralization of lenticulostriate arteries* is another recently described clinic-radiological entity causing subcortical stroke in infants especially following minor injury **(Figs 5A to C)**. Recent reports have also suggested an association between iron deficiency anemia and ischemic stroke, especially in children between 6 months and18 months of age.

Etiology of Posterior Circulation Stroke

Ischemic stroke in posterior circulation (vertebrobasilar arteries and their territories) has slightly different set of causes including vertebral artery dissection following neck trauma, craniovertebral junction anomalies apart from other hematological and prothrombotic states **(Figs 7A to C)**.

Pathophysiology

Thromboembolism is the most common mechanism of stroke with source of thrombus being either the cerebral arteries themselves (vasculitis, vasculopathies, prothrombotic states
Figures 5A to C Mineralizing angiopathy of lenticulostriate arteries with subcortical stroke in infants. (A) Axial, (B) Coronal and (C) Sagittal reconstructions from a multislice brain CT study of a child with mineralizing angiopathy with stroke. *Note:* (A) the hypodensity in right capsuloganglionic region (infarct) with central dot like hyperdensity (mineralized vessel). (B and C) the linear, vertically oriented mineralization along the course of lenticulostriate arteries within the putamina on either side. (B) Subacute infarct is seen in the right putamen, extending superiorly from the terminal part of one of these mineralized vessels
Figure 6 Digital subtraction angiography. Frontal projection of left internal carotid artery injection showing occlusion of the terminal part of internal carotid artery and proximal segments of anterior and middle cerebral arteries (arrowheads). *Moyamoya* collaterals (asterix) are seen, giving a "puff of smoke" appearance

and hematological disorders) or the heart and major vessels (cardioembolism).

The pathophysiology of cerebral ischemia consists of primary and secondary injury. *Primary injury* implies the cellular dysfunction caused directly by ischemic insult. The chain of events and derangements set into motion by the primary injury constitute the *secondary injury*. Prominent in the tissue damage caused by cerebral ischemia is the presence of a *central core*—where ischemia is most severe with rapid development of tissue infarction and neuronal cell death. The area surrounding the central core, which is marginally perfused, is called the *penumbra*. Penumbra has the capacity to recover when perfusion is restored promptly. The balance between cerebral metabolic rate and the supply of oxygen and glucose determines extent of penumbra, and thus the severity of stroke. This has therapeutic implications, in that early restoration of blood flow by thrombolysis may prevent the extent

of neuronal damage, hence, the need for emergent therapies like thrombolysis and other neuroprotective strategies.

Clinical Features

The evolution of symptoms of stroke is often hyperacute to acute in children, i.e., the onset to peak symptoms usually takes hours. This is true especially for embolic strokes. For thrombotic strokes (e.g., following neck trauma and vasculopathies) one may see less abrupt onset or stuttering course, determined by the rapidity of thrombus formation and occlusion or embolization distally. The severity of symptoms is often maximum at onset with gradual improvement thereafter.

The presenting symptoms depend on the anatomical and functional areas of brain affected, and often give clues to likely etiology **(Table 1)**. The common symptomatology includes one or more focal neurological deficits, i.e., hemiparesis (most common presentation), dysarthria, aphasia, gaze palsies, facial nerve palsy, hemianopsia and diplopia. Many children, especially infants and young children, also manifest nonspecific features like headache, drowsiness, irritability and behavioral abnormalities. Isolated extrapyramidal symptoms like hemidystonia may be presenting symptom in infants with subcortical strokes involving perforating arteries.

Differential Diagnosis

Todd's Palsy

Transient weakness of one or more body parts following seizure in those parts, which lasts variably from 30 minutes to 36 hours. Neuronal exhaustion following continuous firing during seizure is the possible explanation for Todd's palsy. Hemiparesis is the most common manifestation and usually resolves completely without any treatment.

Acute Demyelinating Event

Acute disseminated encephalomyelitis (ADEM) is the most common demyelinating event in childhood. Mono or hemiparesis may be the presenting symptom in many cases, often associated with significant encephalopathy. A preceding febrile illness or recent vaccination is the most common trigger. Neuroimaging, especially magnetic
Figures 7A to C Posterior circulation stroke. (A) Axial diffusion weighted and (B) T2 weighted images of the brain showing subacute infarct in the distribution of the left superior cerebellar artery. (C) MR angiogram shows occlusion of the mid and distal thirds of the basilar artery (arrowheads)

Table 1 Salient features: Clues to underlying etiology of stroke

Finding	Likely etiology
History of neck trauma or fall with object in oral cavity	Carotid artery thrombosis with or without dissection, posterior circulation stroke due to vertebral artery dissection
Trivial fall or minor trauma in young children	Lenticulostriate artery mineralization with subcortical stroke
History of blood transfusions	Sickle cell disease
History of recurrent abortions in mother	Anti-phospholipid antibodies (aCL and lupus anticoagulant)
Family history of stroke in young (< 40 years), premature cardiac death, unexplained deep venous thrombosis	Familial hyperlipidemias, inherited prothrombotic states
History of varicella (preceding 6–12 months)	Postvaricella angiopathy
Prior developmental delay	Congenital heart disease and chronic systemic diseases (predominant motor delay), inborn errors of metabolism, mitochondrial cytopathies
Recurrent headaches	Familial hemiplegic migraine, MELAS
Stroke during the course of febrile illness, with encephalopathy	Pyogenic or tubercular meningitis with arteritic infarcts
Antecedent or concurrent respiratory infection	Mycoplasma-associated stroke
Recurrent hemidystonias	Subcortical stroke involving perforating arteries to basal ganglia
Irregular peripheral pulses	Takayasu arteritis
Hypertension (Pre-existent or concurrently developing)	Moyamoya disease (Renovascular hypertension), TTP, SLE
Moderate-severe anemia	Sickle cell disease, iron deficiency anemia, chronic systemic disease
Cardiac murmur	Congenital heart disease, rheumatic heart disease
Facial dysmorphism	Down syndrome (Associated with Moyamoya syndrome and posterior circulation stroke)
Multiple café-au-lait macules	Neurofibromatosis (Associated with Moyamoya syndrome)
Lens dislocation	Homocystinuria, Sulfite oxidase deficiency, Marfan syndrome
Skin rash	SLE, Fabry disease (Angiokeratomas), TTP, Lymphoreticular malignancies
Recurrent strokes	Moyamoya disease, inherited prothrombotic states, metabolic stroke, sickle cell disease, major structural heart disease

Abbreviations: MELAS, mitochondrial encephalomyopathy with lactic acidosis and strokelike episodes; SLE, systemic lupus erythematosus; TTP, thrombotic thrombocytopenic purpura.

resonance imaging (MRI) confirms the nonvascular demyelinating nature of the disorder with predominant involvement of white matter, with or without gray matter involvement.

Strokelike Episodes in MELAS
The focal neurological deficits of acute onset may be seen in this condition. They may be transient or may persist for prolonged periods ranging from days to months. They are attributed to thrombus formation secondary to cellular energy failure in the vascular endothelium. Hence, the infarcts on neuroimaging characteristically do not follow the arterial territories of brain. Elevation of lactate in arterial blood and cerebrospinal fluid (CSF), and lactate peak on magnetic resonance spectroscopy (MRS) suggests this possibility.

Intracranial Space-Occupying Lesions (ICSOL)
Focal symptoms and signs may be a presenting feature of inflammatory granulomas such as neurocysticercosis (NCC) and

tuberculoma, pyogenic brain abscesses, fungal granulomas and brain tumors. Neuroimaging (MRI) helps in differentiating these pathologies.

Posterior Reversible Encephalopathy Syndrome (PRES)

Acute onset encephalopathy with or without neurological deficits in children with acute onset hypertension. It predominantly affects posterior brain regions (parieto-occipital areas)—both gray and white matter, and sometimes brainstem. It usually resolves in days to weeks.

Recurrent Episodic Hemiparesis

Alternating hemiplegia of childhood (AHC) and familial hemiplegic migraine (FHM) are the channelopathies with recurrent episodic weakness. The FHM is an autosomal dominant form of migraine with aura resulting from mutations in calcium ion channel (CACNL1A4). The AHC is another autosomal dominant channelopathy (ATP1A2 mutations) manifesting as recurrent flaccid hemiparesis, often alternating between the sides. Neuroimaging is normal in these conditions, and genetic testing confirms the diagnosis.

Approach to Diagnosis and Evaluation

In children presenting with acute onset neurological deficits, first step is to confirm the vascular nature of pathology, followed by evaluation for possible etiologies and risk factors.

Neuroimaging

Neuroimaging of brain is the cornerstone for arriving at diagnosis of stroke by confirming the vascular nature and ruling out other mimicking conditions. Neuroimaging is indicated as early as possible in children with suspected stroke. The MRI is the most useful imaging modality in ischemic stroke, complemented by magnetic resonance angiography (MRA) and venography (MRV). The computerized tomography (CT) and digital subtraction angio-graphy (DSA) are indicated in specific situations **(Figs 5 and 6)**.

Magnetic Resonance Imaging

The MRI of brain is the gold standard for diagnosis of stroke. It typically includes T1W, T2W, T2-FLAIR and diffusion weighted imaging (DWI) sequences. The DWI is the most sensitive MRI sequence to identify early and small ischemic infarcts in AIS **(Figs 4A and 7A)**. The DWI can pick up abnormalities as early as 4–6 hours. Hence, DWI should always be included in children with suspected stroke. All children with ischemic stroke should also be evaluated with MRA to assess patency of cerebral vessels as well as neck vessels (including carotid arteries and vertebrobasilar system).

Computerized Tomography (CT)

The CT of brain has limited role in evaluation of children with ischemic stroke. One indication for CT in child with suspected stroke is in the setting of significant hemodynamic instability or encephalopathy making the sedation and transport of the child difficult. In emergency situations, CT also helps in ruling out hemorrhagic stroke.

In the recently described entity of lenticulostriate artery mineralization in infants with subcortical stroke, CT is the pre-ferred imaging modality. This condition is suspected when children between 6 months and 24 months present with acute hemiparesis and hemidystonia following trivial fall or minor trauma. While axial CT sections show only hyperdense dots with surrounding hypodensity in the region of basal ganglia, the sagittal

and coronal reconstructed sections clearly demonstrate the linear mineralization of these perforating arteries (linear hyperdensities along vessels) along with infarct (hypodensity) **(Figs 5A to C)**.

Digital Subtraction Angiography (DSA)

It is the gold standard for diagnosis of vasculopathies, hence is performed in children with suspected moyamoya disease, small vessel vasculitis, cervicocephalic arterial dissection and arterial stenosis of other etiologies **(Fig. 6)**.

Transcranial Doppler (TCD)

The transcranial Doppler is a noninvasive test to measure blood flow velocity in major cerebral vessels. It has been well studies in children with sickle cell disease (SCD), to monitor the stroke risk and deciding the need for blood transfusion. Typically, children with time-averaged mean velocity of more than 200 cm/s on TCD have higher risk of stroke. Hence, it is recommended that in children with SCD, periodic TCD should be done: annually if initial TCD is normal, a month later if abnormal, and 3–6 months later if borderline abnormal.

Etiological Evaluation

A thorough clinical evaluation including prior neurodevelopmental status, 3-generation family history, detailed physical and neurological examination, and focused examination of cardiovascular system (especially cardiac murmurs, carotid bruit, peripheral pulses and blood pressure in all four limbs) should be done in all children. The salient clues on history and physical examination are given in **Table 1**.

The risk factors for childhood stroke are multiple and evaluation should be individualized based on the age, family history, type of stroke (AIS or CVST), geographic location and comorbidities, e.g., sickle cell disease, congenital heart disease, head and neck trauma, etc. The necessary investigations are given in **Table 2**. The initial universal investigations (Level 1) are aimed to evaluate for most common causes and treatable causes of ischemic stroke, hence, mandatory in all children. Evaluation of inherited prothrombotic states is desirable in all children with ischemic stroke, but, the necessary investigations from this list may be individualized (Level 2). For example, protein C deficiency, protein S deficiency, antithrombin deficiency, elevated lipoprotein (a), and mutations of factor V Leiden and prothrombin genes are seen with both AIS and CVST, whereas MTHFR polymorphisms and antiphospholipid antibodies are mainly associated with AIS. The Level 3 investigations are indicated in selected children as these are rare causes (Inborn errors of metabolism, collagen vascular disorders and mitochondrial cytopathies) or restricted to certain geographic locations (e.g., Hb-electrophoresis). The prothrombotic investigations like protein C deficiency, protein S deficiency, antithrombin deficiency, elevated lipoprotein (a) should be preferably done at least 3 months after the acute stroke event, to reduce the possibility of falsely low levels of anticoagulant proteins.

MANAGEMENT OF ARTERIAL ISCHEMIC STORKE

Stabilization and Supportive Care

Stroke in children is a neurological emergency and requires multidisciplinary care involving pediatric neurologist, intensivist and the nursing staff. Similar to any medical emergency, the initial part of management includes stabilization of vital functions and supportive care for associated complications and comorbidities. The overview of management of childhood ischemic stroke is given in **Flow chart 1**.

Table 2 Investigations for children with ischemic stroke

Level 1: Mandatory in all children	
Complete blood counts including platelet count and RBC indices, erythrocyte sedimentation rate, C-reactive protein, peripheral smear for RBCs and atypical cells, sickle cell screening, fasting lipid profile, 2D-echocardiogram, ECG, carotid Doppler, liver function tests and renal function tests, serum iron studies	
Level 2: Preferable to do in all children, may be individualized	
Protein C, Protein S, Anti-thrombin III, APCR, Factor V Leiden, plasma homocysteine, anticardiolipin antibodies (aCL-IgM, IgG), Lupus anticoagulant, lipoprotein (a), MTHFR polymorphisms, Prothrombin gene mutations	
Level 3: Indicated in selected children	
Preceding respiratory infection	Mycoplasma serology
Collagen vascular diseases (Chronic systemic features like pyrexia, weight loss, joint pains, lymphadenopathy, cytopenias)	ANA, Anti-ds DNA
Mitochondrial cytopathies (Failure to thrive, recurrent strokes/stroke-like episodes, short stature, respiratory irregularities, myoclonic epilepsy)	Arterial lactate, CSF lactate, muscle biopsy, mitochondrial mutations
Inborn errors of metabolism (consanguinity, siblings affected/died, episodic symptoms)	Ammonia, arterial lactate, blood-TMS, urinary organic acids by GC-MS
Sickle cell disease (Endemic area for sickle cell disease, past history of blood transfusions, severe anemia, hemolytic facies)	Hb-electrophoresis
Failure to thrive, hepatosplenomegaly, recurrent infections	Mantoux test, chest X-ray, retroviral serology
Adolescents with suspected use of illicit drugs	Toxicology screen of blood and urine

Abbreviations: ANA, anti-nuclear antibodies; APCR, activated protein C resistance; CSF, cerebrospinal fluid; DNA, deoxyribonucleic acid; ECG, electrocardiogram; GC-MS, gas chromatography-mass spectrometry; MTHFR, methylenetetrahydrofolate reductase; RBC, red blood cells; TMS, tandem mass spectrometry.

The care of airway, breathing and circulation is of prime importance. The oxygen saturation (SpO_2) should be maintained more than 90% with the use of supplemental oxygen, and if necessary, mechanical ventilation. Aggressive treatment of fever, systemic hypertension, hypoglycemia and hypovolemia should be done (as per standard protocols) as they help in maintaining adequate cerebral perfusion and meet cerebral energy requirements. In children with sickle cell disease and stroke, adequate hydration and exchange transfusion to keep HbS more than 30% is the mainstay of treatment. The neurological complications like seizures and raised intracranial pressure should also be managed aggressively. This will help further in limiting the cerebral neuronal injury caused by ischemia. The raised intracranial pressure may be treated using either mannitol or hypertonic saline (3% saline) in the acute phase and hyperventilation for shorter periods. Rarely, emergent decompressive craniectomy may be needed in cases with malignant cerebral edema not responding to medical measures and with impending risk of herniation. There is no evidence to suggest beneficial effect of hypothermia in children with stroke. There is no role of prophylactic anticonvulsants in the absence of clinical or electrographic seizures.

Thrombolytic Therapy

So far, there is no conclusive evidence to suggest the safety and efficacy of thrombolytic therapy (tPA: tissue plasminogen activator) in children with ischemic stroke.

Anticoagulant Therapy

Acute Phase Anticoagulation

Most of the available guidelines suggest use of anticoagulation agents (Unfractionated heparin or low molecular weight heparin, i.e., LMWH) for anticoagulation in the acute phase in conditions which might benefit substantially. For example, carotid artery or vertebral artery dissection, structural heart disease, vasculopathies like carotid/vertebral artery dissection, and suspected inherited prothrombotic states where the risk of propagating thrombus or recurrence risk is considered to be higher. It is usually continued till the evaluation for etiology of stroke is completed. The LMWH has several advantages: fewer side effects and drug interactions, less need for monitoring, and easy to administer (subcutaneous route).

Long-term Anticoagulation

Based on the information on etiology and risk factors in an individual child, the risks and benefits of long-term anticoagulation (3–12 months or more) are assessed. It is recommended for children with substantial risk of recurrent stroke. The anticoagulants are safe and effective for secondary prevention of ischemic stroke in children. After the neonatal period, anticoagulant therapy is recommended for stroke prevention in children. The indications for long-term use of anticoagulants include major structural heart disease with risk of recurrent cardio embolism (to be continued till repair of defect), carotid artery dissection, and inherited prothrombotic states. The options include LMWH and Warfarin. When initiating warfarin, both heparin and warfarin are used together with overlap of few days till INR of 2.0–3.0 is reached, and the heparin is then discontinued. The schedule and doses of anticoagulants and antiplatelet drugs are given in **Table 3**.

Antiplatelet Drugs

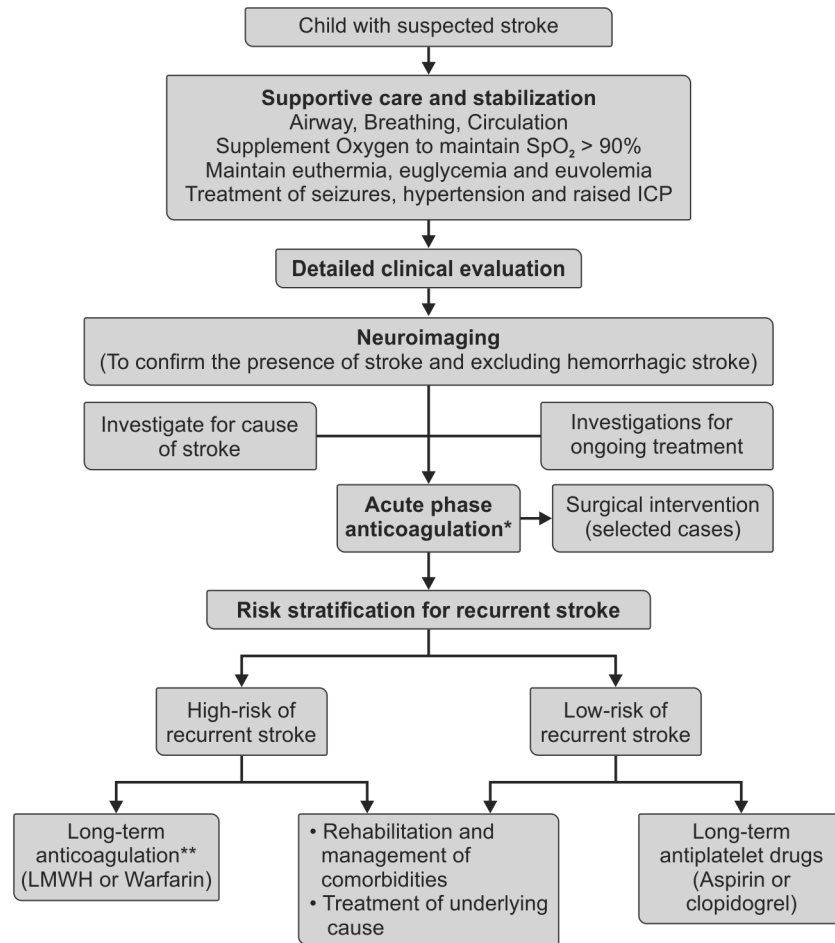
In children who are not on anticoagulants, aspirin or clopidogrel are reasonable choices for secondary prevention of recurrent stroke for a period of 12–60 months. These are indicated in children who are assessed to have a lower risk of recurrent embolism or prothrombotic states **(Table 3)**. In children who are advised long-term aspirin therapy, varicella vaccination and annual influenza vaccination is recommended to reduce the risk of Reye syndrome.

Surgical Management

Revascularization surgeries (direct and indirect techniques) are recommended as the first line measure for preventing recurrent strokes in moyamoya disease/syndrome. Emergency decompressive craniectomy may be considered in children with ischemic stroke and malignant cerebral edema (impending herniation) or posterior circulation stroke compromising the brainstem functioning. This may be helpful only if done in the earliest stages before permanent brainstem dysfunction occur. The likely benefits of reducing intracranial pressure should be weighed against the possibility of long-term neurological morbidity (vegetative state) of the survivors.

Rehabilitation and Chronic Management

The rehabilitation is initiated during the acute period (whenever child is hemodynamically and neurologically stable) and

Flow chart 1 Overview of management of ischemic stroke in children


* Acute phase anticoagulation can be considered in all children with AIS and CVST pending etiological investigations. It is definitely indicated in those with carotid artery dissection, complex structural heart disease and propagating thrombus of any cause
** For a variable duration ranging between 3 months and 12 months or longer depending on the persistence of recurrence risk

Table 3 Dosages of medications in ischemic stroke

Drug	Dose
LMWH: Enoxaparin	*Infants < 2 months:* 1.5 mg/kg/dose; subcutaneous; 12 hourly *Children > 2 months:* 1.0 mg/kg/dose; subcutaneous; 12 hourly (Half of the above doses are used as prophylactic dose)
LMWH: Dalteparin	*All age groups:* 150 U/kg/day; subcutaneous
Unfractionated heparin	*Loading:* 75 U/kg IV over 10 minutes *Maintenance:* 28 U/kg/h (Infants < 1 year); 20 U/kg/hour (> 1 year) Titrate dose to maintain target aPTT between 60 and 85

Warfarin	Day 1: 0.2 mg/kg/day single dose
	Day 2–4: Titrated based on INR (Target > 3.5)
	  1–1.4: Repeat day 1 dose
	  1.5–3.0: Increase by 50%
	  3.1–3.5: Increase by 25%
	> 5th day: Target INR: 2–3
	  1.1–1.4: Increase by 20%
	  1.5–2.0: Increase by 10%

Aspirin	3–5 mg/kg/day as single dose; Oral
Clopidogrel	1 mg/kg/day; Oral

Abbreviation: LMWH, low molecular weight heparin.

continued during the follow-up period till optimum functional status is reached. The team includes physiotherapy (strengthening of weak muscles, stretching of spastic muscles, gait training, oromotor stimulation to improve swallowing, etc.), occupational therapy (helping for activities of daily living, feeding and hand function), child psychologist (treatment of behavioral problems and family counseling), speech therapist, and use of orthoses and other assistive devices where needed. Newer rehabilitation techniques like modified constraint-induced movement therapy (CIMT) is useful for children with hemiparesis. The transcranial magnetic stimulation (TMS) is another technique often being used in rehabilitation of adults with stroke. Its utility is still being researched in pediatric stroke rehabilitation.

The long-term management also includes treatment of comorbidities like epilepsy, learning difficulties, dysarthria, behavioral problems like hyperactivity, inattention, aggressive behavior, etc.

Prognosis

Stroke in children entails significant long-term neurological morbidity and mortality (5–20%). The common neuropsychomotor impairments includes motor developmental delay, gait disturbances, epilepsy, learning difficulties, feeding and swallowing difficulties, drooling and scholastic difficulties from various factors. The severity and multiplicity of these morbidities is related

to the underlying cause and risk factors as well as the extent of cerebral neuronal damage. The factors predicting poor outcomes include presence of multiple risk factors, involvement of cerebral cortex, associated systemic illness, large size of infarct, and moyamoya disease.

The recurrence rate of ischemic stroke in children is 10–25% with associated higher risk of mortality. The recurrence risk is higher in children with multiple co-existing risk factors. Hence, it is advisable to evaluate for all risk factors even when one risk factor is identified on initial investigations.

CEREBRAL VENOUS SINUS THROMBOSIS

The clinical presentation often include nonspecific features like altered sensorium, seizures, headache, intracranial hemorrhages (subdural, subarachnoid or intraparenchymal), hydrocephalus, and pseudotumor cerebri. Pathophysiologically, the CVST also results in events similar to arterial occlusion. Since venous occlusion results in increased venous pressure, there is a tendency for blood vessels to rupture producing secondary hemorrhage. This may also cause a marked increase in intracranial pressure.

Apart from the risk factors associated with AIS, there are unique associations with CVST including dehydration, head and neck infections (mastoiditis, rhinosinusitis, and meningitis), beta thalassemia, drugs like L-asparginase and erythropoietin-alpha, and iron deficiency anemia. The prothrombotic states are found in up to 2/3rd of children with CVST.

MRI with MRV is the preferred imaging modality in children with suspected CVST **(Figs 2A to C)**. Secondary hemorrhages are often seen along with the ischemic infarcts in the draining areas. In the absence of significant hemorrhages, acute phase anticoagulation with unfractionated heparin or LMWH is recommended for CVST in children. The anticoagulation with LMWH or Warfarin is usually continued for 3–6 months, with duration depending on the extent of recanalization of venous sinuses in follow-up.

Apart from monitoring development, these children should be specifically followed-up for ophthalmological sequelae including reduced visual acuity and visual field defects.

HEMORRHAGIC STROKE

The common causes of hemorrhagic stroke other than trauma include vascular malformations (arteriovenous malformations, cavernous malformations, and aneurysms), coagulopathies, thrombocytopenia, brain tumors, and rarely, hypertension **(Figs 8**

and 9). The onset of symptoms is more dramatic and progression much faster in hemorrhagic stroke as compared to ischemic stroke.

The common presenting symptoms includes acute onset severe headache, vomiting and rapid worsening of sensorium due to raised intracranial pressure. The damage caused by intracranial hemorrhage is three folds. First, collection of blood may act as space occupying lesion and can worsen the rise in intracranial pressure. Second, disruption of blood brain barrier also promotes development of cerebral edema. Third, presence of blood and erythrocyte breakdown products may add to the pre-existing damage and can sometime result in hydrocephalus.

Children with nontraumatic hemorrhage should be evaluated to look for cause of hemorrhage including neuroimaging (MRI, MRA and 4-vessel angiography in selected cases), coagulation defects, platelet count, etc.

Management includes initial stabilization and supportive care, correction of coagulation defects and thrombocytopenia if identified. The surgical evacuation of hematoma may be beneficial in children with large posterior fossa hematomas, and large supratentorial hematomas with midline shift and impending herniation. In children with vascular malformations, definitive therapy of malformations is advised in those with higher risk of rebleeding. The therapeutic options include endovascular or

IN A NUTSHELL

1. Ischemic stroke is the most common form of stroke in children.
2. The etiology and risk factors for childhood stroke are much more diverse as compared to stroke in adults.
3. Structural heart disease and hematological disorders are the most common causes around the world.
4. Infection is an important risk factor for childhood stroke in developing countries.
5. All attempts should be made to identify as many as risk factors as possible. This helps in secondary prevention.
6. The presenting symptoms may be nonspecific in infants and young children.
7. Arterial dissections, structural heart disease with continued risk of embolism and inherited prothrombotic states are indications for anticoagulation therapy in acute phase (LMWH) as well as long-term (Warfarin).
8. Anti-platelet drugs are the mainstay of secondary prevention for most cases of childhood stroke.
9. Rehabilitation is an essential component of long-term care of children with stroke.

Chapter 42.15
Pyogenic Meningitis
B Talukdar

Pyogenic meningitis is one of the important causes of mortality and cerebral damage in infants and children; 90% of the reported cases occur in children between 1 month and 5 years of age. Relative deficiency in host defense mechanism appears to be the cause of this selective age predilection. In India about a decade back, 1.5% of hospital admissions were due to bacterial meningitis and the case fatality rate was 16%; this probably holds good even today. Globally, the median incidence for acute bacterial meningitis is projected as 34.0 (16.0–88.0) per 100,000 child-years, with a median case-fatality rate of 14.4% (5.3–26.2%) in a recent survey based on 71 studies categorized by 6 World Health Organization regions.

ETIOLOGY

The most common organisms causing pyogenic meningitis in children beyond the neonatal period are similar worldwide and include *Haemophilus influenzae type B*, *Streptococcus pneumoniae* and *Neisseria meningitidis*. About 90% of the cases of pyogenic meningitis are caused by these three bacteria. Of these three organisms, most common is *S. pneumoniae* followed by *H. influenzae* and then *N. meningitidis.* Preventive immunization in early childhood has however changed this pattern in some places; in USA *Haemophilus* has been virtually wiped out and *N. meningitidis* is now the most common pathogen causing pyogenic meningitis.

The most common serotypes of *S. pneumoniae* that cause invasive disease are 4, 6B, 9V, 14, 18C, 19F and 23F. The most common type of *H. influenzae* is type b out of its 6 serotypes. Invasive disease due to *N. meningitides* is caused by the strains of groups A, B, C, Y and W-135; in India most common cause is group A strain, group B strain is rare. Other organisms are *Staphylococcus aureus, E. coli, Klebsiella, Proteus, Acinetobacter, Pseudomonas* and *Salmonella. Staphylococcus* is often seen in association with pyoderma. *Pseudomonas* usually is an opportunistic infection commonly seen in presence of immunocompromised states like malignancy, immunodeficiency disorders, malnutrition, etc.

The organisms causing acute bacterial meningitis in India, based on a few reports in Indian literature [included are series with sample size > 50 and only the cerebrospinal fluid (CSF) culture positive cases] and occurring in varying frequency (percentage out of culture positive cases only) are as follows: *S. pneumoniae* (3.1–44.7%), *Staphylococcus aureus* (11.11–31.3%), *Neisseria meningitides* (3.1–21.2%), *Haemophilus influenzae type b* (9.4–26%), *S. aureus* (1.5–11.11%), *Klebsiella pneumoniae* (1.5–6.9%), *Citrobacter freundii* (12.5%), Group. B. Streptococci (9.5%), *E coli* (3.1–7.5%), *Pseudomonas aeruginosa* (1.5–6%), alpha hemolytic *Streptococcus* (0.74–5.5%), *Morexella* spp (5.5%), anaerobes (5.5%), *Salmonella typhimurium* (3–3.1%), *micrococci* (3.1%), *Streptococcus pyogenes* (3.1%), *Acinetobacter* spp (3.1%), *Proteus rettgeri* (3.1%), *Salmonella havana* (3.1%), Group B beta hemolytic *Streptococcus* (1.48%), *Proteus* (1.4%). It is important to note that culture positivity (which is the gold standard for etiological diagnosis) in all these studies are poor varying from 23.5% to 68.5%, majority hovering around 30%. All these organisms occur sporadically; *N. meningitides* is known to cause epidemics off and on.

PATHOGENESIS AND PATHOLOGY

There is varying degree of inflammation of the leptomeninges. The bacteria gain entry into the meninges through different routes namely (1) hematogenous, (2) contiguous, (3) direct implantation and (4) malformations having communication with CSF space. Hematogenous route is the most common route; the blood stream infection usually occurs as a part of a generalized bacteremia and septicemia without any definite focus or from some focus of infection elsewhere in the body like pyoderma, abscess, pharyngotonsillitis, bacterial endocarditis, osteomyelitis and otitis media. Infection through contiguity is seen in scalp cellulitis and abscess, mastoid abscess, osteomyelitis of scalp bones and vertebrae. Direct implantation can occur in scalp fracture, fracture cribriform plate, vertebral fracture. Recurrent pyogenic meningitis is often associated with congenital malformations, shunts and fracture of the cribriform plate and following cochlear implants.

The pathologic hallmark of pyogenic meningitis is accumulation of purulent exudate in the subarachnoid space over the cerebral hemispheres, sulci, gyri, base of the brain and basal cisterns. There is edema of the brain involving the white matter, compressed ventricles or at times dilated ventricle (due to obstruction of the CSF flow by exudates). Purulent exudate often shows bacteria and extends into cortex, cerebellum, brainstem, spinal cord along perivascular spaces. Choroid plexus shows purulent material.

The inflammatory exudate frequently engulfs/damages the meningeal, cortical and subcortical blood vessels causing thrombosis, impairing cerebral circulation. This often results in focal necrosis that may get infected resulting focal micro-abscesses. Vascular occlusion can also result from small infective microthrombi. The inflammatory exudate frequently engulfs/damages cranial nerves coming out of the brain. One immediate net effect of the inflammation and exudation is intracranial hypertension with its ill effects. Invasion of the leptomeninges by bacteria is associated with breach of the blood brain barrier and a cascade of body's reactionary defense mechanisms occur.

All these result in severe alteration in cerebral metabolism and homeostasis. Studies of the pathophysiology of bacterial meningitis have suggested that the development of neuronal injury is related to the release of vasoactive substances or alteration of blood-brain barrier permeability. Cerebral edema, increased intracranial pressure (ICP), systemic hypotension, decreased cerebral perfusion pressure, vascular inflammation, thrombosis and a variety of other vascular changes may result in global or regional reductions in cerebral blood flow (CBF), which contribute to this insult. Approximately one-third of infants and children with bacterial meningitis will have markedly reduced CBF, and even in those children with normal total flow, regional hypoperfusion is common. Reduced CBF is associated with cerebral edema and a poor prognosis.

Cerebral damage can affect various areas of the gray matter, white matter, cerebral pathways resulting in variety of sequelae. Hydrocephalus can develop secondary to obstruction to CSF circulation due to adhesion and fibrosis in the communicating canals (obstructive hydrocephalus) or secondary to reduced absorptive surface in pia-arachnoid (communicating hydro-cephalus).

CLINICAL MANIFESTATIONS

Common presenting *symptoms* are fever, seizures, abnormal behavior, refusal to feed and vomiting. The most important *signs* are (1) altered sensorium and (2) classic signs of meningeal

irritation. Altered sensorium can manifest as irritability, lethargy, obtundation, stupor and coma. At times the child may be delirious and makes shrill cry. The signs of *meningeal irritation,* i.e., neck rigidity, Kernig sign and Brudzinski sign are seen in varying frequency.

Signs of *intracranial hypertension* include headache, vomiting, papilledema, cranial nerve palsy (commonly 3rd, 4th and 6th nerve), hypertonia, hyper-reflexia, extensor plantar response, frequent vomiting (often forceful) and seizures. Bulged anterior fontanel is a very good sign of intracranial hypertension in infants if it is open. Features of herniation should be carefully looked for (dilated pupil, cranial nerve palsy, irregular respiration, continuous depression of sensorium). Brainstem herniation can cause death, which may be precipitated by lumbar puncture.

Focal deficits are also not seen uncommonly at presentation— like cranial nerve palsy, hemiplegia, paraplegia, etc. *Hypertension* is usually due to intracranial hypertension. *Hypotension* is usually seen in association with sepsis and dehydration. *Shock* may result from septicemia, dehydration, severe intracranial hypertension or a combination of these factors. Shock is common in meningococcemia often associated with adrenal involvement.

Other *nonspecific signs* of infection include fever and tachycardia. Features of associated diseases like pneumonia, diarrhea, pyoderma and otitis media can be seen and may mislead the clinician regarding the correct diagnosis. Certain clinical findings can give etiologic clue and should be kept in mind, i.e., rash (meningococcal meningitis), pneumonia (pneumococcal meningitis), otitis media (*H. influenzae* type B/pneumococcal meningitis), pyoderma, cellulitis, boils (staphylococcal meningitis), immunodeficiency disorder (*Pseudomonas* and other uncommon organism).

DIAGNOSTIC INVESTIGATIONS

Essential investigations are (1) CSF examination to demonstrate inflammation of the meninges and (2) recovery of the organism causing the inflammation through culture of CSF and Gram stain. Confirmed diagnosis however rests only on recovery of the bacteria from CSF.

The CSF is often turbid to varying extent, total cell count is raised with predominance of polymorphonuclear cells, protein is raised and sugar is low. Chloride may be normal to low depending upon status of hydration and vomiting. Most important and almost consistent diagnostic pointers in CSF are marked polymorphonuclear pleocytosis and low sugar (supposed to be due to consumption by bacteria/increased utilization by cerebral tissue). CSF sugar is usually less than CSF to blood sugar ratio which is usually 66%. Recovery of the organisms is through CSF culture and Gram stain. CSF smear can give positive results in as much as about 60–90% cases in expert hands.

It is better to repeat the lumber puncture (LP) after 48–72 hours if the LP is traumatic. The CSF be examined as soon as possible within 30 minutes, otherwise cells may degenerate and give fallacious count. Chances of getting a positive culture also may be reduced as some bacteria may die in external environment. Delayed inoculation into the culture media also may reduce the chances of growth. In India CSF culture positivity rate is usually low in most of the reported studies probably due to prior use of antibiotic and suboptimal laboratory techniques. Multiplex polymerase chain reaction is a promising new technique for etiological diagnosis of pyogenic meningitis.

Blood culture is essential in all cases. Other diagnostic aids are based on serology and antigen detection techniques. Currently the most useful ones are latex agglutination and PCR. These however cannot be a substitute for culture as they cannot give the antibiotic sensitivity of the pathogen, which is important for treatment.

The total leukocyte count (TLC) is usually high with polymorphonuclear leukocytosis and raised ESR. C-reactive protein (CRP), procalcitonin (PCT) and nonspecific markers of infection are often quite high and may help in differentiating it from viral and tubercular meningitis. Neuroimaging (CT or MRI) can detect intracranial hypertension, subdural effusion and empyema, ventriculitis, hydrocephalous, infarct, and abscess.

DIFFERENTIAL DIAGNOSIS

The most important conditions that need to be differentiated are viral *meningitis* and *encephalitis. Complex febrile convulsions* can look like pyogenic meningitis. However, a nontoxic look and normal to mildly altered sensorium that recovers quickly strongly points towards CFS. *Cerebral malaria* can mimic pyogenic meningitis at times; endemicity, presence of splenomegaly, no sign of meningeal irritation points towards it. *Brain abscess* may have focal features and often papilledema. Stroke following upper respiratory infection often with fever also may mimic pyogenic meningitis; again lack of sign of meningeal irritation, less toxicity, focal deficit with clear localization (hemiplegia) right from onset and findings related to the etiology like splenomegaly, murmur are pointers towards stroke. Some cases of *tubercular meningitis* (TBM) may have acute onset like pyogenic meningitis (mostly those having some complication). TBM should be suspected in presence of history of contact, splenomegaly, lymphadenopathy and focal deficit; detail history usually reveals duration of illness to be longer.

Analysis of the CSF is helpful diagnosis of viral meningitis and TBM in most cases. The most important findings in CSF in viral meningoencephalitis are lymphocytic pleocytosis and normal sugar and sterile culture and in TBM are lymphocytic pleocytosis, sugar that is low but not too low, and sterile culture. CSF sugar can be low in mumps meningoencephalitis and Japanese encephalitis. The CSF can be hemorrhagic at times in herpes simplex encephalitis. It needs to be noted that in practice CSF finding often show quite a lot of variability from normal creating difficulty in etiologic diagnosis, i.e., whether it is really pyogenic meningitis, viral meningitis or TBM. In some cases of pyogenic meningitis protein or sugar may be normal and even it may be acellular. In a series on meningitis having only CSF culture positive cases (n = 100), protein was normal in 22 (22%), sugar was normal in 21%, CSF was acellular in many but culture grew organisms.

TREATMENT

Antibiotic Therapy

Instituting treatment of pyogenic meningitis is considered as a medical emergency as it has been well established that later the antibiotic treatment, poorer is the outcome. The odds for unfavorable outcome may increase by up to 30% per hour of treatment delay. Hence, it is the practice to start antibiotic empirically once pyogenic meningitis is diagnosed without waiting for culture reports. Antibiotic therapy is subsequently modified after receiving the culture reports.

Initial Empirical Therapy

It is started with antibiotics that cover the most common bacteria and have good penetration into the CSF space. This can be achieved by third generation antibiotics cefotaxime and ceftriaxone. In infants beyond neonatal period and till about 3 months of life gram-negative organisms are common. It is usual to start cefotaxime and aminoglycosides like gentamicin/amikacin in

this age group. Doses of commonly used antibiotics for pyogenic meningitis are provided in **Box 1**.

Development of antibiotic resistance is a problem and has to be always kept in mind and changes have to be made accordingly. In USA *S. pneumoniae* has shown some resistant to cefotaxime and ceftriaxone in about 25% of isolates. Because of this it is often a practice to add vancomycin right from beginning in the empiric therapy. In India such resistance has not been reported.

If the meningitis is suspected to be due to *S. aureus* then vancomycin is added to the empirical therapy. If *Pseudomonas* is suspected ceftazidime is a good choice. Other antibiotics that are effective against some or other bacteria causing pyogenic meningitis should be kept in mind in cases of development of resistance or unsatisfactory response as these may have to be added under specific circumstances. Some such antibiotics that have been used in pyogenic meningitis are methicillin (*Staphylococcus*), nafcillin (*Staphylococcus*), meropenem (difficult cases), ampicillin (Group B *Streptococcus*, *Pneumococcus*, *Meningococcus*, some strains of *H. influenzae*, and *Listeria. monocytogenes*) and chloramphenicol (*H. influenzae, Salmonella*). Penicillin G (*S. pneumoniae*, *Meningococcus*), is practically not used due to difficult administration, side effects and development of resistance.

Duration of Antibiotic Therapy

Usually 10 days are believed to be sufficient in most children with uncomplicated pyogenic meningitis who show a good response to treatment. If response is not satisfactory it is a practice to continue antibiotic longer or modify treatment after repeating LP. Longer duration of treatment (2–3 weeks) is preferred in gram-negative and *Staphylococcus* infections. However, if clinical condition is satisfactory and CSF is sterile antibiotic can be stopped earlier. Prolonged duration of therapy up to 4–6 weeks may be indicated for subdural empyema and ventriculitis.

Repeat LP is usually not needed in uncomplicated pyogenic meningitis. It is prudent to do a repeat CSF examination if response is unsatisfactory after about 72 hours; if CSF shows deterioration specially showing increased cellularity, antibiotic is often revised at this point.

Revision of antibiotic after starting the empirical therapy is done on the basis of culture and sensitivity report. In culture negative cases if there is no response or deterioration in clinical condition, antibiotic may be revised keeping in mind the culture sensitivity pattern of the suspected pathogen.

Supportive Treatment

During acute stage the complications—*dehydration, electrolyte disturbance, seizures, respiratory failure and shock* have to be managed appropriately. Fluid therapy should be tailored according to the hydration status and presence of raised intracranial pressure. There is no need for routine fluid restriction. As per a Cochrane review some evidence supports giving full maintenance intravenous fluids rather than restricted in the first 48 hours, in settings with high mortality rates and where patients present late.

Intracranial hypertension needs to be handled properly; mannitol and dexamethasone are commonly used. *Subdural effusion/empyema* usually does not need additional treatment except if it causes marked intracranial hypertension when tap has to be done.

H. influenzae type B and *S. pneumoniae* meningitis have been shown to be associated with significant hearing loss. Corticosteroids significantly reduced severe hearing loss in children with *H. influenzae* meningitis (RR 0.34, 95% CI 0.20–0.59) but not in children with meningitis due to non-Haemophilus species; it also reduced neurological sequelae, but did not reduce overall mortality. No significant adverse effect was seen except recurrence of fever. Dexamethasone (0.15 mg/kg/dose IV 6 hourly for 4 days) thus should be administered first dose starting before the first dose of antibiotic if meningitis is suspected to be due to *H. influenzae*. With increased thrust of immunization with HiB vaccine the role of dexamethasone is limited

Routine/daily monitoring should include general condition, vital signs, mental status with GCS, appearance of new signs, status of hydration and feeding, fluid, electrolytes and output. Cranial USG that can be done easily is a very useful tool for objective monitoring. During prolonged antibiotic therapy it is important to monitor for side effects like drug rash, renal functions (vancomycin), and USG for gall stone (ceftriaxone). Keeping in mind the complication of hearing loss, all patients at discharge should undergo hearing test; this may help appropriate rehabilitation of some cases.

OUTCOME

Mortality in bacterial meningitis seems to vary from 10% to 30% based on a few reported studies from India. In USA it is around 1–5% at present. Sequelae include a variety of neurodevelopmental, cognitive and motor dysfunctions like mental insufficiency (often subtle), learning disorders, speech, hearing and visual disorders, and behavior problems. These complications need to be managed appropriately.

PREVENTION

Vaccines against *H. influenzae* (Hib), *S. pneumoniae* and *N. meningitidis* have been introduced in many countries. Hib vaccine has proven to be most effective. In USA where Hib vaccine is a part of the routine infant immunization schedule, *H. influenzae* has now been virtually eradicated as a cause of childhood meningitis. Vaccines have also been introduced for pneumococcal infections and seem to be quite promising. Vaccination aimed at reducing *N. meningitidis* infection is under evaluation.

Prophylactic strategy aimed at preventing development of meningitis by these common organisms in contacts is in place and should be followed. Rifampicin prophylaxis (20 mg/kg/day for 4 days) is given to all household contacts of *H. influenzae* meningitis. Chemoprophylaxis with rifampicin (10 mg/kg/dose) every 12 hours for 2 days should be given to close contacts in cases of *N. meningitidis*.

IN A NUTSHELL

1. About 90% of the cases of pyogenic meningitis are caused by *Streptococcus pneumoniae*, *Haemophilus influenzae* type B, and *Neisseria meningitidis*.
2. The bacteria gain entry into the meninges by hematogenous route, contiguous spread, direct implantation, and through malformations having communication with CSF space.
3. The pathologic hallmark of pyogenic meningitis is accumulation of purulent exudate in the subarachnoid space over the cerebral hemispheres, sulci, gyri, base of the brain and basal cisterns.
4. Common presenting symptoms are fever, seizures, abnormal behavior, refusal to feed and vomiting. The most important signs are altered sensorium and classic signs of meningeal irritation.
5. Signs of intracranial hypertension include headache, vomiting, papilledema; 3rd, 4th and 6th, cranial nerve palsy, hypertonia, hyperreflexia, extensor plantar response and seizures.
6. The CSF is often turbid to varying extent, total cell count is raised with predominance of polymorphonuclear cells, protein is raised and sugar is low.
7. Initial empirical therapy is started with third generation antibiotics (cefotaxime or ceftriaxone). Treatment is given intravenously for minimum 10 days.

Chapter 42.16
Tuberculosis of the Central Nervous System
Chandrakanta, Rashmi Kumar

Central nervous system tuberculosis (CNS TB) is a devastating illness which carries a high mortality and morbidity. Disease is caused by *Mycobacterium tuberculosis* and primarily affects young children. Co-infection with human immunodeficiency virus (HIV) and the emergence of drug resistant strains further complicates the picture.

BURDEN OF DISEASE

About 1% of total TB cases and 5–10% of extra pulmonary TB cases develop CNS tuberculosis. Incidence is higher in young children and HIV infected patients. The estimated mortality of tuberculous meningitis in India is about 1.5 per 100,000 population. Risk factors for CNS tuberculosis include younger age, HIV co-infection, malnutrition, recent measles or pertussis infection, the use of immunosuppressive agents and high disease prevalence in the community.

PATHOGENESIS

According to the widely accepted theory, CNS tuberculosis occurs as a result of secondary hematogenous spread from the site of primary extracranial tuberculous lesion, which is frequently in the lung, and not because of direct hematogenous spread. This secondary hematogenous spread occurs early in infection before adaptive immune responses control the infection. Rich and Mc Cordock in 1933 suggested a two stage model. Small tuberculous lesions (Rich's foci) develop around bacteria seeded in the brain during the initial hematogenous dissemination. These initial foci may be in the meninges, the subpial or subependymal surface of the brain or the spinal cord and are most commonly situated in the sylvian fissure. These foci may remain dormant for years after initial infection. Subsequent rupture or growth of these foci results in various type of CNS tuberculosis. Rupture into the subarachnoid space or into the ventricular space leads to meningitis. Sizeable inoculation or absence of an adequate cell-mediated immunity is thought to be the cause of parenchymal cerebral tuberculous foci developing to tuberculoma or tuberculous brain abscess. How the bacteria leave the lung, enter the brain and cause cerebral pathology is not clear.

Immunological factors are probably responsible for the rupture or growth of these foci. A lower number of CD4 T lymphocytes have been found in children with tuberculous meningitis (TBM) as compared to children who had primary pulmonary complex only. Recently association of distinct *Mycobacterium tuberculosis* strains with CNS disease has been found. Indo-Oceanic or East Asian Beijing lineages are more likely to cause meningitis than Euro-American lineages. A bacterial gene known as *pknD*, that encodes for serine/threonine protein kinase required for invasion of cells lining the brain endothelium has been identified.

CLASSIFICATION OF NEUROTUBERCULOSIS

Neurotuberculosis has a wide range of presentations, including tuberculous meningitis, tuberculoma, tuberculous abscess, spinal TB and tuberculous encephalopathy. Out of these TBM is the most common form, found in 70–80% of the cases of neurotuberculosis. Classification of CNS tuberculosis is given in **Table 1**.

Table 1 Classification of CNS tuberculosis

Intracranial	Tuberculous meningitis
	Serous tuberculous meningitis
	Tuberculous encephalopathy
	Tuberculous vasculopathy
	Localized tuberculous meningitis
	CNS tuberculoma (single or multiple)
	Tuberculous brain abscess
Spinal	*Osseous spinal TB*
	Pott's spine and Pott's paraplegia
	Nonosseous spinal TB
	Spinal tuberculoma
	Isolated spinal TBM
	Tuberculous radiculomyelopathy (usually associated with TBM)

Abbreviations: CNS, central nervous system; TB, tuberculosis; TBM, tuberculous meningitis.

TUBERCULOUS MENINGITIS

It usually occurs within the first 3–6 months after the primary infection. After the release of tubercle bacilli from granulomatous lesions into the subarachnoid space, dense gelatinous exudates are formed predominantly around the sylvian fissures, basal cisterns, brainstem and cerebellum. It is hypothesized that these exudates are localized to the basilar areas simply as a result of the normal flow pattern of CSF. Of note, Rich foci typically follow the vascular pattern and they are not preferentially distributed to the basilar areas of the brain where the exudates are typically located. Direct contact of the exudates leads to a border zone reaction in the underlying brain parenchyma. Blockage of CSF pathways is responsible for the development of hydrocephalus in TBM. This blockade can be at basal cisterns, outflow of 4th ventricle or cerebral aqueduct. Commonly it is due to (1) blockage of the basal cisterns and medullocerebellar angles causing obstruction to the flow of the CSF in the subarachnoid spaces by dense basal exudates and/or (2) interference in the absorption of CSF by the arachnoid granulations. Aqueduct is usually dilated but sometimes it can be occluded because of compression by edematous portion of midbrain or tuberculoma or exudates and edema.

Vascular involvement is common and occurs because of inflammation, thrombosis or external compression by exudates. Vasculitis develops in the vessels of the circle of Willis, the vertebrobasilar system and the perforating branches of the middle cerebral artery resulting in infarctions in the distribution of these vessels. Vessels of the circle of Willis are more frequently involved than the vessels of the basilar system. Sylvian fissure and the basal ganglion are the most common sites of infarction. Infarctions are located in the distribution of medial striate and thalamo-perforating arteries in majority of patients. Cranial nerves are involved as a result of entrapment neuropathy caused by thick exudates.

Clinical Presentation

Early diagnosis of TBM is difficult because of nonspecific clinical features, and disease is often diagnosed late when brain damage has already occurred. In children peak incidence is between 2 years and 4 years and it is unusual below 6 months of age. Youngest case reported was a 3 months old child.

Typically TBM has a subacute onset with a gap of 1–4 weeks or more between onset of fever and the onset of neurological symptoms. Early symptoms are nonspecific and include poor weight gain, low-grade fever, vomiting, photophobia and listlessness. Headache occurs less often than the adults. As the

disease progresses meningeal irritation signs, altered sensorium, seizures, signs of raised intracranial pressure, cranial nerve palsies, focal deficits, and abnormal movements are seen. **Table 2** shows common clinical features at presentation of TBM. A family history of tuberculosis can be identified in about half of children. Cranial nerve palsies are found in 30–50% cases and sixth nerve is most commonly involved. Vision loss can occur due to optochiasmatic arachnoiditis, third ventricle compression of optic chiasma or optic nerve granuloma. Fundoscopy may reveal papilledema and choroid tubercles. Choroid tubercles are mostly associated with miliary tuberculosis and found in only 10% cases without miliary tuberculosis. These are yellow lesions with indistinct borders (single or cluster) and are virtually pathognomonic of tubercular etiology. Grading of the severity of TBM according to modified British Medical Research Council (1948) clinical criteria is given in **Table 3**.

Diagnosis of TBM can neither be made nor excluded on the basis of clinical features alone but they are helpful in making the diagnosis. In a study in children it was found that persisting fever for more than 6 days, optic atrophy, focal neurologic deficit, abnormal movements, and CSF leukocyte differential of less than 50% neutrophils were the clinical variables predictive of TBM. The diagnostic sensitivity and specificity were 98% and 44% respectively when one feature was present. When three or more features were present sensitivity was 55% and specificity was 98%. For adult patients of TBM in Vietnam diagnostic rule was developed which has reported sensitivities of 96–98% and specificities ranging from 68% to 88%.

Two uncommon forms of TBM are serous TB meningitis and TB encephalopathy.

Serous TBM
Serous TBM is characterized by signs and symptoms of mild meningitis seen especially in BCG vaccinated children. These children present with fever, headache and vomiting and may be conscious at the time of presentation. Disease is mostly localized and CSF examination is normal. A study on 107 bacteriologically proven TBM cases found a normal CSF in 15% cases.

Table 2 Tuberculous meningitis clinical features on presentation

Clinical feature	Percentage
Headache	50–80%
Fever	60–95%
Vomiting	30–60%
Photophobia	5–10%
Anorexia	60–80%
Neck stiffness	40–80%
Confusion	10–30%
Coma	30–60%
Any cranial nerve palsy	30–50%
Cranial nerve III palsy	5–15%
Cranial nerve VI palsy	30–40%
Cranial nerve VII palsy	10–20%
Hemiparesis	10–20%
Paraparesis	5–10%
Seizures	50%

Table 3 Severity of tuberculous meningitis (Modified MRC scale)

Stage I	Alert and orientated without focal neurological deficit
Stage II	Glasgow coma score 14–10 with or without focal neurological deficit or Glasgow coma score 15 with focal neurological deficit
Stage III	Glasgow coma score less than 10 with or without focal neurological deficit

From: van Toorn R, Springer P, Laubscher JA, Schoeman JF. Value of different staging systems for predicting neurological outcome in childhood tuberculous meningitis. Int J Tuberc Lung Dis. 2012;16(5): 628-32.

Tuberculous Encephalopathy
This variant of cerebral tuberculosis has been reported in Indian children with diffuse cerebral disorder. Presenting symptoms were coma, convulsions, involuntary movements and pyramidal signs with normal CSF findings. Postmortem examination of brain showed diffuse cerebral edema, perivascular myelin loss and sometimes hemorrhagic leukoencephalopathy. These features may be more typical of a postinfectious allergic encephalomyelitis. Other postulations are hypersensitivity to tuberculous protein, isoimmunization, and cerebral microangiopathy. Few reports suggest that disease is responsive to corticosteroid treatment but no controlled trial has been done.

Differential Diagnosis
Many CNS infections have presentation similar to tuberculous meningitis. In particular TBM may be confused with partially treated pyogenic meningitis, viral encephalitis, typhoid encephalopathy, brain abscess, brain tumor and chronic subdural hematoma. These should be ruled out by appropriate investigations as required. Diagnostic criteria for the classification of definite, probable or possible tuberculous meningitis on the basis of clinical features, CSF findings, neuroimaging and other laboratory tests have been used, mainly for research purposes.

Laboratory Diagnosis
Cerebrospinal fluid (CSF) examination and neuroimaging are helpful in confirmation of diagnosis of TBM **(Box 1)**. CSF examination typically shows predominantly lymphocytic reaction (50–500 white cells per mL) with raised protein levels (0.8–4 g/L). CSF sugar is low, mostly less than two-thirds of serum glucose concentration. CSF lactate is about 5–10 mmol/L. In early TBM polymorphonuclear cells may be predominant, which is replaced by lymphocytes later on. CSF profile of TBM mimics a large list of infectious and noninfectious meningitic processes.

Definite diagnosis requires demonstration of tubercle bacilli in the CSF either by smear examination with Ziehl-Neelsen stain (sensitivity 10–25%) or by bacterial culture (sensitivity 18–83%). Ventricular fluid has highest detection rate of positivity. HIV infected individuals have more number of tubercular bacilli in CSF than noninfected individuals so positivity is higher. Following methods increase the yield of CSF smear examination—examination of at least 10 mL CSF, repeated samples examination, CSF taken before or shortly after starting treatment, centrifuging at

BOX 1 List of investigations to diagnose central nervous system tuberculosis

1. Laboratory diagnosis (CSF sample):
   a. CSF microscopy and CSF protein and sugar estimation
   b. ZN staining for acid fast bacilli
   c. Culture and sensitivity for *Mycobacterium tuberculosis*
   d. ISMA
   e. NAAT and other PCR assays (e.g., INNO-LiPA Rif.TB and Xpert MTB/RIF)
2. Neuroimaging––MRI/CT scan of brain/spine
3. Tests to detect evidences of tuberculosis elsewhere in the body:
   a. Chest X-ray
   b. Tuberculin test
   c. *M. tuberculosis* AFB stain/culture from another source (i.e., sputum, lymph node, gastric lavage, etc.)
   d. Commercial *M. tuberculosis* NAAT from extra-neural specimen
   e. CT/MR/ultrasound evidence for TB outside the CNS

Abbreviations: CSF, cerebrospinal fluid; ISMA, immunocytochemical staining of mycobacterial antigens; AFB, acid-fast bacillus; NAAT, nuceic acid amplification test; PCR, polymerase chain reaction; CNS central nervous system

relative high centrifugal force for 20 minutes, careful examination for at least 10–20 minutes. A thorough investigation should be done to isolate acid-fast bacillus (AFB) from other sites like gastric aspirate, fine needle aspiration of lymph node and peritoneal or pleural fluid.

Use of the immunocytochemical staining of mycobacterial antigens (ISMA) in the cytoplasm of CSF macrophages has shown some promising results. It is based on the assumption that in initial stage of infection, bacilli are ingested by the macrophages and during the second stage bacilli grow logarithmically within newly recruited macrophages. Consequently, the positivity of the test indicates that viable *M. tuberculosis* isolates are present in CSF. A study has demonstrated its sensitivity of 73.5% and specificity of 90.7% with positive and negative predictive values of 52.9% and 96.0% respectively.

As it is difficult to detect tubercle bacilli in the CSF, a number of other tests have been developed. These tests include the evaluation of adenosine deaminase activity (ADA), interferon-gamma (IFN-γ) release by lymphocytes, and *M. tuberculosis* antigens and antibodies.

The ADA activity test is a rapid test that represents the proliferation and differentiation of lymphocytes as a result of the activation of cell-mediated immunity after *M. tuberculosis* infection. In patients with TBM, it was found that ADA activity could not distinguish between TBM and other types of bacterial meningitis, but that it could help once meningitis due to different pathogens has been ruled out. ADA values from 1 to 4 U/L (sensitivity > 93% and specificity < 80%) can help to exclude TBM and values more than 8 U/L (sensitivity < 59% and specificity > 96%) can improve the diagnosis of TBM ($p < 0.001$).

Measurement of IFN-γ release by lymphocytes stimulated by *M. tuberculosis* antigens has been found useful for the diagnosis of latent TB and extrapulmonary TB. However, in TBM it has shown variable results from study to study. Liao et al. found that the test was 100% sensitive and 100% specific, whereas other authors reported a very poor value of the test in diagnosing TBM.

Tests which detect mycobacterium specific antigen and antibodies in CSF are rapid and less expensive but have poor sensitivity and specificity. Also, these tests can not differentiate acute from the past infection. For the antibody assay sensitivity and specificity are 52–93% and 58–99% respectively. Detection of various *M. tuberculosis* antigen markers, such as lipoarabinomannan, purified protein derivatives, heat shock protein of 62 kDa and 14 kDa, GroE, Ag 85 complex and 38 kDa antigen have been tried to confirm TBM diagnosis. For various antigen assays reported sensitivity and specificity are 38–94% and 95–100% respectively.

Commercially available nucleic acid amplification test (NAA) and other polymerase chain reaction (PCR) assays are rapid tests but sensitivity and specificity depends on the primer used for the test. When primer against IS 6110 is used for PCR, sensitivity is 76% and specificity is 89%. A systematic review concluded that commercial NAA assay can confirm TBM (98% specificity) but cannot rule it out (sensitivity 56%). Xpert MTb/RIF assay have been used for rapid diagnosis of TBM (sensitivity 67–85% and specificity of 94–98%).

NEUROIMAGING

Neuroimaging is helpful in both diagnosis and management of TBM. Magnetic resonance imaging (MRI) of brain is superior to a CT scan particularly when brainstem is involved. Diffusion weighted MRI can detect early infarcts and border-zone encephalitis (cytotoxic edema that underlies the tuberculous exudates). Leptomeningeal tubercles are visualized in about 90% of children by the Gadolinium enhanced MRI. Magnetic resonance imaging is also valuable for the identification and monitoring of associated cranial neuropathies like optochiasmatic arachnoiditis requiring urgent treatment. MR angiography can be used to identify vascular involvement.

CT scan brain may be normal in up to 30% cases of early TBM but abnormal in most of cases with late TBM. CT scan reveals hyperdense basal exudates in noncontrast film **(Fig. 1)**. Contrast enhanced film shows basal meningeal enhancement, infarcts, hydrocephalus and tuberculomas. A study revealed that basal meningeal enhancement, ventriculomegaly, tuberculoma, and infarcts as characteristics to distinguish CNS tuberculosis from pyogenic meningitis and proposed that basal meningeal enhancement, tuberculoma, or both were 89% sensitive and 100% specific for TBM.

TREATMENT OF CNS TUBERCULOSIS

Medical Management

Chemotherapeutic regimens for TBM are based on expert opinion rather than evidence. Most of the guidelines follow a model of treatment of pulmonary tuberculosis. Different treatment regimens for treatment of TBM are given in **Box 2**. Rifampicin, isoniazid,
Figure 1 Meningitis with thick exudates and mild hydrocephalus

---

BOX 2 Treatment of central nervous system tuberculosis

1. Supportive treatment (particularly in TBM cases)
   a. Maintenance of airway breathing and circulation
   b. Intravenous fluid therapy—Isotonic fluids like dextrose normal saline
   c. Maintenance of acid base and electrolyte balance
   d. Antiepileptic drugs for control of seizures
   e. Treatment of raised intracranial pressure-–-intravenous mannitol/3% saline infusion, acetazolamide, glycerol and diuretics. In refractory cases hyperventilation and urgent surgical intervention should be considered.
   f. Prevention of other complications in a comatose child, e.g., exposure keratitis, aspiration pneumonia, bed sore etc.
2. Specific treatment—Antituberculous therapy along with corticosteroid treatment (various guidelines are given in **Table 5**)
3. Surgical treatment
   a. Ventriculoperitoneal shunt or endoscopic third ventriculotomy for hydrocephalus if indicated
   b. Surgical decompression in case of Pott's paraplegia
   c. In case of large tuberculoma causing mass effect and tuberculous brain abscess

Abbreviation: TBM, tuberculous meningitis.

pyrazinamide and ethambutol are the main drugs used for TBM treatment. Pyrazinamide and isoniazid are freely distributed in CSF. Rifampicin, ethambutol and streptomycin do not enter CSF but may penetrate inflamed meninges. In CNS tuberculosis daily therapy should be preferred particularly in intensive phase. Few observational studies have shown good results with intermittent drug therapy under DOTS program, but controlled trials have not been done. Current WHO guidelines state that TBM should be treated by 2RHZE followed by HR for 10 months. There are promising data to suggest that increasing the intensity of treatment, through use of high-dose intravenous rifampicin and the addition of moxifloxacin, can enhance bacterial killing and improvement in outcome. **Tables 4 and 5** show 1st line and 2nd line antituberculous drugs for CNS tuberculosis.

Multidrug-Resistant TBM

It is extremely difficult to suspect multidrug resistant (MDR) TBM except in a situation when a contact is a case of MDR TB. In high burden countries probability of a patient with TBM having MDR tuberculosis would be 0.1–1.4%. Association of MDR TBM with

Beijing strains and drug resistance related mutations in katG and rpoB genes has been found. Standard culture methods to test drug susceptibility are too slow to help in deciding treatment plan and most patients have usually died before results are available. Therefore CSF NAATs and detection of genetic mutations that confer drug resistance, e.g., Xpert MTB are the only way to diagnose drug resistance quickly.

In a study, fatality rate of MDR TBM was found 57% with significant functional impairment in most of the survivors. Isoniazid monoresistant disease requires addition of another drug with better CSF penetration. MDR TBM is treated with extended course of second line drugs. These drugs are less effective and have more side effects than a rifampicin and isoniazid based regimen. WHO guidelines recommend that an injectable drug (e.g., amikacin, capreomycin) with a fluoroquinolone (e.g., moxifloxacin), and at least two other active drugs should be used during initial phase of treatment of multidrug-resistant pulmonary tuberculosis. Choice of drug should be determined by probable susceptibility and CSF penetration. Because ethionamide and cycloserine have good CNS penetration, they

Table 4 Guidelines for the treatment of CNS tuberculosis in infants and children

Revised National Tuberculosis Control Program/ Indian Academy of Pediatrics (2010)	Rifampicin 10 mg/kg/day (max 600 mg) for 8–9 months Isoniazid 5–10 mg/kg/day (max 300 mg) for 8–9 months Pyrazinamide 30–35 mg/kg/day (max 2 g) for 2 months Ethambutol 20 mg/kg/day (max 1 g) for 2 months Prednisolone 2–4 mg/kg/day for 2–4 weeks followed by tapering doses for 2 weeks
British Infection Society (2009)	Isoniazid 10–20 mg/kg/day (max 500 mg) orally for 12 months Rifampin 10–20 mg/kg/day (max 600 mg) orally for 12 months Pyrazinamide 30–35 mg/kg/day (max 2 g) orally for 2 months Ethambutol 15–20 mg/kg/day (max 1 g) orally for 2 months Prednisolone 4 mg/kg/day orally for 4 weeks, followed by a reducing course over 4 weeks
American Thoracic Society, CDC, and Infectious Diseases Society of America (2006)	Isoniazid 10–15 mg/kg/day (max 300 mg) orally for 9–12 months Rifampin 10–20 mg/kg/day (max 600 mg) orally for 9–12 months Pyrazinamide 15–30 mg/kg/day (max 2 g) orally for 2 months Ethambutol 15–20 mg/kg/day (max 1 g) orally for 2 months Dexamethasone 8 mg/day/day orally for children weighing less than 25 kg and 12 mg/day for children weighing 25 kg or more for 3 weeks, followed by a reducing course over 3 weeks
World Health Organization (2014)	Isoniazid 10 (7–15) mg/kg/day (max 300 mg) orally for 12 months Rifampin 15 (10–20) mg/kg/day (max 600 mg) orally for 12 months Pyrazinamide 35 (30–40) mg/kg/day (max 2 g) orally for 2 months Ethambutol 20 (15–25) mg/kg/day orally for 2 months Prednisone 2 mg/kg/24 hour orally for 4 weeks, followed by a reducing course over 1–2 weeks

Table 5 Recommended daily dosages of second-line anti-tuberculous drugs for treatment of tuberculous meningitis in infants and children

Name of drug	*Doses*	*CSF penetration*
Ethionamide	20 mg/kg/day (max 1 g) oral single dose	Good
Cycloserine	10–15 mg/kg/day (max 1 g) oral single daily dose	Good
Streptomycin	20–40 mg/kg/day (max 1 g) IM or IV single daily dose	Poor but penetrate inflamed meninges
Para-aminosalicylic acid	200–300 mg/kg/day orally in 2–4 doses	No data
Capreomycin	15–30 mg/kg/day (max 1000 mg) orally single daily dose	No data
Amikacin and Kanamycin	15–30 mg/kg/day (max 1 g/day) IM or IV as a single daily dose	Poor but penetrate inflamed meninges
Ofloxacin	15–20 mg/kg/day (max 800 mg) orally as a single daily dose	Not as good as levofloxacin and moxifloxacin
Levofloxacin	7.5–10 mg/kg/day (max 500 mg) orally single daily dose	Good
Moxifloxacin	7.5–10 mg/kg/24 hours (max 500 mg) orally single daily dose	Good
Ciprofloxacin	20–30 mg/kg/24 hours (max 1.5 g) orally single daily dose	Not as good as levofloxacin and moxifloxacin

may be used as part of *intensive-phase* treatment regimen in patients with suspected MDR TBM.

Corticosteroids in CNS TB

Role of corticosteroids in TBM is a controversial issue but a recent Cochrane systemic review concluded that addition of corticosteroid to the treatment reduced the risk of death and disabling residual neurologic deficit. Adverse events were less severe particularly hepatitis. So, it should be used irrespective of patient's age and stage of the disease except in HIV infection. In unstable patients intravenous dexamethasone may be added till oral steroids can be added by oral/nasogastric tube. In some patients response is dramatic with rapid improvement in headache, sensorium and CSF abnormalities. Some argue that corticosteroids by decreasing the meningeal inflammation will lead to decrease CSF penetration of antitubercular drugs. But, in a clinical trial use of corticosteroids did not reduce the CSF concentration of any of the antituberculous drugs.

Preliminary data suggest that the beneficial effect of adjunctive corticosteroids may be augmented by aspirin and predicted by a polymorphism in a gene responsible for eicosanoid synthesis. In a study aspirin resulted in insignificantly lesser number of strokes and significantly reduced 3 months mortality in patients with TBM. Thalidomide, which has an anti-inflammatory and immunomodulatory action, has been rarely used as adjunctive treatment in neurotuberculosis, especially in patients with tuberculous abscesses, tuberculous-related optochiasmatic arachnoiditis and nonresponding tuberculomas.

Treatment of Complications

Aggressive and appropriate management of raised intracranial pressure (ICP), hydrocephalus, vasculitis, acute seizures and hyponatremia can minimize the secondary brain injury.

Hyponatremia

Low serum sodium levels are found in 35–65% cases of TBM. Causes of hyponatremia in TBM include cerebral salt wasting syndrome (CSWS), syndrome of inappropriate antidiuretic hormone secretion (SIADH) and increased renal sensitivity to ADH. Hyponatremia is associated with increased mortality and morbidity in these children. Volume and sodium replacement is performed for the treatment of CSWS. Mineralocorticoid supplementation has also been shown to be effective. For SIADH fluid restriction is done and in case hyponatremia is severe, 3% normal saline along with furosemide is added.

Acute Seizures

Acute seizures occur in about 50% of children. Phenytoin is the most frequently used AED for acute management of seizures. Many antiepileptic drugs interact with antituberculous drugs and may affect metabolism of each other. Also, some antiepileptic drugs are hepatotoxic (sodium valproate) as are antitubercular drugs.

Vasculitis

Corticosteroids may be beneficial because of their anti-inflammatory effect.

Raised Intracranial Pressure (ICP)

Multiple factors are responsible for increased ICP and include cerebral edema due encephalitic process, infarcts with edema, hydrocephalus, tuberculomas and electrolyte disturbances. Osmotic agents like mannitol and hypertonic saline are used to lower the ICP particularly in those patients who do not require surgery.

Treatment of Hydrocephalus

Hydrocephalus is found in more than 80% of children with TBM at presentation. Clinical signs of raised intracranial pressure are poorly associated with presence of hydrocephalus on neuroimaging, so neuroimaging should be done in all children to exclude hydrocephalus. About 80% of children with communicating hydrocephalus can be managed by the medical treatment (acetazolamide and furosemide) only. Failed medical treatment and noncommunicating hydrocephalus are the indications for the ventriculoperitoneal shunting. Endoscopic third ventriculostomy has become an alternative surgical option to divert CSF flow without complications of shunt. Success rates of this procedure are roughly 65%. Failure of the procedure is often caused by distorted anatomy of the third ventricle floor and the fact that hydrocephalus presents during the acute phase of the disease, rather than being post infectious. However, there is no clear cut consensus about timing of CSF diversion surgeries. Many time arrest of hydrocephalus occur even in patients with gross hydrocephalus with medical treatment only.

Paradoxical Worsening During Treatment

Sometimes size of the tuberculomas or meningeal inflammation increases or new tuberculomas appears in TBM during treatment with antituberculous therapy. Mostly these are noticed accidentally by a follow up CT scan performed routinely or when new neurological signs develop during the course. Similar changes have been observed in isolated intracranial and spinal tuberculomas. Resolution of the lesions occurs with continued treatment and steroid therapy probably has a preventive role.

TBM in HIV Patients

Coinfection with HIV does not alter the clinical presentation of TBM, but number and nature of complications may be different. In these patients basal meningeal enhancement and hydrocephalus on CT scan are less common. They have higher number of bacilli in meninges so positivity of CSF AFB staining and culture is relatively high. Active extrameningeal tuberculosis is more common and case fatality rate is as high as 60%. Corticosteroids are not indicated with antituberculous drugs in HIV infected patients. If antiretroviral therapy is started early along with antitubercular drugs, chances of drug toxicity is increased and immune reconstitution inflammatory syndrome can develop. Delayed antiretroviral therapy could allow opportunistic infections to occur and complicate the picture. In a series of 34 patients, 16 developed immune reconstitution syndrome after a median duration of 14 days of starting antiretroviral drugs. Worsening headache and neck stiffness were the common manifestations. Corticosteroids are the mainstay of treatment of TBM associated IRIS, with interruption of antiretroviral therapy reserved for life threatening situation.

OUTCOME AND PROGNOSIS

Clinical stage of TBM at which treatment has been started is the single most important determinant of the outcome for survival and sequelae. Young age, malnutrition, hydrocephalus, focal neurological deficit, miliary disease, underlying debilitating disease and HIV infection are associated with bad prognosis. Mortality and morbidity is very low if treatment is started in stage I, while in stage III almost 50% of patients die, and survivors have some form of neurological deficit. Various sequelae occur in 10–85% of cases TBM. They are intellectual disability, epilepsy, neurological deficits, cranial nerve palsy (commonly 7th, 3rd and 6th cranial nerves), blindness, deafness, behavior problems, and hydrocephalus. Hypothalamic disturbances can lead to precocious

puberty, diabetes insipidus, obesity, Frolich syndrome and growth retardation later on. Intracranial calcifications which are detectable after 2–3 years are found in 20–48% of patients with TBM.

INTRACRANIAL TUBERCULOMAS

Tuberculomas are spherical, granulomatous masses thought to arise when tubercles in the brain parenchyma enlarge without rupturing into the subarachnoid space. They often occur in the absence of TBM but may be found along with TBM. Size varies 2–8 cm in diameter. It may contain necrotic caseous material and tuberculous bacilli inside. Surrounding brain parenchyma is compressed and shows edema and gliosis. In developing countries children and young adults are commonly affected. Clinical presentation depends on the site and size of the tuberculoma. In children infratentorial tuberculomas are more common. Supratentorial tuberculomas present with fever, headache, vomiting, seizures, focal neurological deficit and papilledema. Infratentorial tuberculomas present with cerebellar signs, multiple cranial nerve palsies and brainstem syndromes.

CT findings are a low or high density rounded or lobulated mass and show intense, homogeneous or ring enhancement with contrast. Wall is irregular with perilesional edema. Target sign if present is considered as pathognomonic of tuberculoma **(Fig. 2)**. This is a central calcification or nidus surrounded by a ring that enhances on contrast administration. On CT scan, tuberculomas are often confused with neurocysticercosis (NCC). Inflammatory granuloma size more than 20 mm, irregular outline, marked perilesional edema leading to midline shift and presence of focal neurological deficits are the features of tuberculomas, which can differentiate a tuberculoma from NCC.

On MRI, a non-caseating granuloma is hypointense on T1 weighted image, hyperintense on T2 weighted image and homogeneously enhancing on contrast administration. A caseating granuloma is hypointense or isointense on both T1 and T2 weighted images and ring enhancement is found on contrast administration. Variable degree of perilesional edema is found. In case of central liquefaction, center is hypointense on T1 and hyperintense on T2 weighted images with a surrounding hypointense ring. Ring enhancement is found on contrast administration. MR spectroscopy may help in diagnosis of tuberculoma as it shows a lipid peak.

Mostly diagnosis is made by radioimaging, but a stereotactic diagnostic biopsy can help in establishing accurate diagnosis.

Figure 2 Tuberculoma in left middle cerebellar peduncle near the 4th ventricle

SPINAL TUBERCULOSIS

Pott's Spine and Pott's Paraplegia

It occurs because of tuberculous infection of vertebral bodies and found in less than 1% patients of TB. Thoracic region is most commonly involved (65%) and lumbar (20%), cervical (10%), thoracolumbar (5%) and rarely atlantoaxial region may be involved. Infection of vertebral bodies starts from the bone adjacent to an intervertebral disc or sub periostium anteriorly. Subsequently collapse of vertebral body along with anterior wedging and paraspinal abscess formation occur. Paraspinal abscess leads to compression of the spinal cord. Sometimes neurological deficits are because of dural invasion by the granulation tissue **(Fig. 3)**, or compression by the debris of sequestrated bone, a destroyed intervertebral disc or dislocated vertebra. Rarely cause can be vascular due to anterior spinal artery involvement.

Disease is more common in males and young persons. Subacute, progressive sometimes acute, sensory motor paraparesis is found in 27–47% patients at presentation. Locally there is pain and tenderness over involved spine. There may be bony deformity like gibbus formation and a palpable paraspinal abscess.

Spinal X-rays are usually adequate to show vertebral bodies destruction and reduced intervertebral disc spaces. Other investigations like MRI, CT scan, myelography are often required to decide level and extent of bony involvement, paravertebral abscess and cord compression. CT-guided needle biopsy should be done if required to rule out other etiology. Majority of cases with Pott's paraplegia require surgical decompression along with ATT. Treated cases of Pott's spine may develop paraparesis later on also because of stretching of the spinal cord by a deformed canal.

Nonosseous Spinal Cord Tuberculoma

A review of 74 cases of nonosseous tuberculous paraplegia revealed that extramedullary tuberculomas were the cause in 64%, arachnoid lesion without dural involvement in 8%, and extradural-extramedullary lesions in 8% of cases. Intramedullary tuberculomas are rare. Clinical features resemble extramedullary or intramedullary tumor. Tuberculoma may be found at more than one site. MRI is the investigation of choice for these lesions.

Spinal Tuberculous Meningitis

Spinal TBM may develop when Rich's focus ruptures into the spinal arachnoid space rather than the basal meninges. It can present

Figure 3 Kyphosis due to collapse of D9–D10 vertebra with epidural granulation tissue causing cord compression

acutely or in a chronic form. Fever, headache, and radiating root pain accompanied by myelopathy are the features of acute form. Chronic variety is usually localized to a few segments and presents with progressive spinal cord compression. On examination patchy upper motor neuron and lower motor neuron signs are found. MRI shows CSF loculation and obliteration of the spinal sub arachnoid space with loss of outline of spinal cord in the cervicothoracic region and matted nerve roots in the lumbar region. It gives an appearance of *burnt candle*. There may be associated syrinx formation.

Tuberculous Radiculomyelopathy

It is also known as tuberculous arachnoiditis. Spinal cord and nerve roots are surrounded by the inflammatory exudates but not infiltrated by exudates. Neuronal injury occurs by direct compression and ischemia caused by small vessels involvement with periarteritis. Involvement can be focal, multifocal or diffuse. Clinical features of involvement of spinal cord or nerve root or both may be present. Myelography shows characteristic findings in the form of poor flow of contrast material with multiple irregular filling defects, cyst formation and sometimes spinal block. CSF findings are similar to a case of chronic meningitis, occasionally a dry lumbar tap.

Antitubercular drugs with steroid are the treatment. Surgery is required in case of medical treatment failure.

PREVENTION OF CNS TUBERCULOSIS

Although BCG vaccination and INH prophylaxis have a preventive role, an improved tuberculosis control worldwide would be more effective. Protective efficacy of BCG was not measured by any controlled trial and debate surrounding the efficacy of BCG vaccine has been ongoing since it was first developed. BCG does not provide complete protection and all forms of tuberculosis can occur in BCG vaccinated children. BCG efficacy is around 60–80% in protecting against TBM as found in various studies. Two recent meta-analyses also concluded that BCG vaccination protects against TBM. BCG-vaccinated children who do develop TBM have a milder clinical course and better short-term outcomes than do their unvaccinated counterparts. This could be attributable to a better immunological response induced by BCG vaccination. Prompt treatment of adult tuberculosis cases and INH prophylaxis is crucial in reducing incidence of childhood tuberculosis including CNS tuberculosis.

IN A NUTSHELL

1. CNS tuberculosis continues to be an important cause of neurologic handicap in developing countries.
2. Early diagnosis is difficult because of nonspecific symptoms in TBM.
3. Current laboratory diagnostic tests lack sensitivity to diagnose TBM.
4. Corticosteroids reduce risk of neurodisability and death in HIV-uninfected children.
5. Treatment of tuberculous hydrocephalus depends on the level of the cerebrospinal fluid obstruction.
6. Early diagnosis and treatment of TBM is the single most important factor determining outcome.

Chapter 42.17
Viral Encephalitis
Mary Iype

Encephalitis is an inflammation of the brain, and the most common etiology of encephalitis is viral infection. There are many viruses identified as the causative organism. Some cause epidemics, some are sporadic infections and a few are endemic to certain regions. In the developing world, vector breeding is facilitated due to poor environmental hygiene; and this, concurrent with the poor host immunity and vaccination coverage, make encephalitis a significant public health issue.

EPIDEMIOLOGY

The incidence of encephalitis for tropical countries ranges from 1.77 to 6.34 per 100,000 and for Western countries, the incidence is 0.5 to 7.4 per 100,000. The incidence of herpes simplex encephalitis (HSE) is 0.2–0.4 per 100,000; and accounts for 5–10% of all encephalitis. Another important causative organism of encephalitis in India is *Japanese B encephalitis (JE) virus.* Some outbreaks of encephalitis in India include enteroviruses (EV) 89, 76 in east Uttar Pradesh in 2006; EV 71 in Lucknow in 2008; Sporadic EV 71 (2004–2006) in Uttar Pradesh and the epidemic of EV 71 in 2007 in Delhi. There were outbreaks of Chandipura virus in Andhra Pradesh in 2003; in Gujarat in 2004; in Nagpur in 2005 and 2007 and sporadic cases from 2005 to 2006 in Andhra Pradesh. Nipah virus encephalitis epidemics were reported in 2001 and 2007 from West Bengal.

ETIOLOGY

Viruses that cause encephalitis include herpes simplex virus (HSV) types 1 and 2, varicella zoster virus (VZV), Epstein-Barr virus (EBV), cytomegalovirus (CMV), human herpes virus (HHV) types 6 and 7, Coxsackie viruses, Echoviruses, EV 70 and 71, Parechovirus, Poliovirus, measles virus, mumps virus, human immunodeficiency virus (HIV), influenza viruses, Adenovirus, Parvovirus, lymphocytic choriomeningitis virus, Rubella virus, West Nile virus, La Crosse virus, St Louis virus, Powassan encephalitis virus, Venezuelan, Eastern and Western equine encephalitis viruses, Colorado tick fever virus, Dengue virus, Rabies virus, Louping ill virus, Rift Valley fever virus, Crimean-Congo hemorrhagic fever virus, Chikungunya, Murray Valley encephalitis virus and Japanese encephalitis virus.

The viruses that are common in Asia are Japanese encephalitis virus, West Nile virus, Dengue virus, Murray Valley encephalitis, Rabies virus, Chikungunya virus, Nipah virus, Kyasanur Forest disease virus, Chandipura virus, EV, Herpes, measles, mumps, VZV, and EBVs.

PATHOGENESIS

Viruses access the central nervous system (CNS) by either the neuronal or hematogenous route. The latter is most common and in arthropod-borne infections is associated with alterations of the blood-brain barrier. Access to CNS by the intraneuronal route occurs typically in rabies where the virus reaches the limbic system by traveling along the nerves, and in HSV infections. Rabies virus may reach the brain by inhalation when a person enters a cave infested with infected bats or inhalation from aerosols in the laboratory. Following the bite, the Rabies virus which has an affinity for nicotinic receptors invades the muscle. It is not known for certain whether the virus invades the muscle spindles or the motor end plates; or whether the superficial sensory nerve endings are invaded. The virus travels by retrograde axoplasmic flow to reach the cell body of the nerve invaded. Once in the CNS, the gray matter is first invaded.

Enteroviruses spread by the fecal oral route and first replicate in the Peyer's patches in the intestine. In acute viral encephalitis, a remarkable pathological finding is the infiltration of mononuclear inflammatory cells in the Virchow-Robin spaces and in the meninges around the wall of vessels (perivascular cuffing). With further disease progression, astrocytosis proliferation and hypertrophy of microglial cells with formation of microglial aggregates (microglial nodules) and neuronophagia (clusters of microglial cells surrounding a dead neuron) become prominent histopathological findings.

HHV-6, has two variants, A and B. Both of them are neurotropic in vivo and reside latently in macrophages; complicating attempts to link HHV-6 to neurological disease. However, HHV-6 is considered a possible cause of encephalitis in immunosuppressed children. EBV remains latent in B lymphocytes, the exact mechanism of activation of the Epstein-Barr viral genome resulting in encephalitis is controversial.

Herpes simplex encephalitis Unlike other viral encephalitis, there is no viremia. The virus traverses mucous membranes and then travels by retrograde axonal transport to the trigeminal ganglion, where it remains dormant. There is periodic activation and anterograde axonal transport to allow viral shedding and infection of new hosts. Spread through the olfactory nerve endings is also postulated.

Japanese B encephalitis Soon after the mosquito inoculates a patient, there is viral multiplication in the skin; this results in viremia and later invasion of the nervous system. The exact mechanism of penetration of the brain is unknown.

CLINICAL FEATURES

Encephalitis or another CNS infection should be suspected in a child with fever, altered behavior or consciousness, new onset seizures, or neurological deficits. Inflammatory demyelinating diseases like acute disseminated encephalomyelitis, acute renal failure, hepatic failure, intoxication with drugs or poisons, Reye syndrome, autoimmune encephalitis, and cortical venous thrombosis may be considered as differential diagnoses depending upon the clinical scenario. The onset of the illness, any other associated medical illness, telltale evidence of other illness like an odor, rashes or signs of trauma should be picked up. The constellation of presenting symptoms, the course of illness and the findings on examination should be analyzed systematically to arrive at a diagnosis and to plan investigations.

If the patient with encephalitis has concomitant myocarditis, pleurodynia, herpangina or hemorrhagic conjunctivitis an enterovirus should be suspected. Signs of hemorrhage may also be seen with Dengue virus, Yellow fever virus and Rift Valley fever virus.

Children with JE are known to present with mutism. Tremor and other involuntary movements are noted with fever. Fever abates in 2–3 weeks when the involuntary movements become more obvious and occur in the form of choreoathetosis or ballism.

Presence of movement disorders, orofacial dyskinesias, seizures that are resistant to treatment and a subacute onset should point to an autoimmune encephalitis and the appropriate investigations should be planned. **Table 1** shows the possible etiologic agent based on the clinical presentation.

If the patient who presented with an acute encephalitic syndrome shows features of neuritis or myeloneuritis, EBV should be entertained as a possible etiological agent. Ophthalmoplegia, autonomic and sensory neuropathy are seen in EBV encephalitis. Subacute encephalitis may be seen in CMV encephalitis.

Measles can present with four different encephalitic pictures: acute encephalitis, postviral encephalomyelitis, measles inclusion

Table 1 Possible viral etiological agents based on clinical presentation

Clinical presentation	Possible etiological agent
Cerebellar ataxia	Varicella zoster virus
Dementia	HIV, measles virus
Poliomyelitis-like flaccid paralysis	Japanese B virus, poliovirus, enteroviruses, West Nile virus, tick-borne encephalitis virus
Extrapyramidal manifestations	Japanese B virus, West Nile virus, Nipah virus
Retinitis	CMV, West Nile virus
Rash	VZV, HHV-6, rubella virus, measles virus, hand foot and mouth disease
Diarrhea	Enterovirus
Respiratory tract findings	H1N1 and other influenza viruses, adenovirus
Parotitis	Mumps virus
Lymphadenopathy	HIV, EBV, CMV, measles virus, rubella virus

Abbreviations: CMV, cytomegalovirus; EBV, Epstein-Barr virus; HHV, human herpes virus; VZV, varicella zoster virus.

BOX 1 Differential diagnosis of viral encephalitis

- Autoimmune encephalitis
- Sjögren syndrome
- Hashimoto's thyroiditis
- Systemic lupus erythematosus
- Acute disseminated encephalomyelitis
- Vasculitis of CNS
- Bulbar variant of Guillain-Barré syndrome
- Primary and metastatic brain tumors
- Metabolic and toxic diseases
- Nonconvulsive status
- Reye syndrome.

---

body encephalitis, and subacute sclerosing panencephalitis (SSPE). Acute encephalitis presents with fever, rash, cough, coryza, and Koplik spots. Cerebrospinal fluid (CSF) shows pleocytosis and EEG usually shows nonspecific slowing. Postviral encephalomyelitis refers to a demyelinating illness occurring within 2 weeks of the rash and consists of altered mental status, seizures, and focal neurological deficits. Measles inclusion body encephalitis presents with dementia, behavioral abnormalities, myoclonus, seizures and even coma. Death occurs in a few weeks after onset. SSPE is a rare late complication of measles presenting with decreasing school performance, behavioral abnormalities and a characteristic slow myoclonus. Gradually there will be affection of the pyramidal and extrapyramidal tracts with macular pigmentary degeneration.

Rabies encephalitis often has to be distinguished from demyelination after rabies vaccine given as postexposure prophylaxis. The features that help one to distinguish rabies encephalitis from postvaccinial demyelination would include presence of hydrophobia or/and aerophobia, autonomic features like salivation, and rapid progression which favor rabies. MRI of the brain shows grey matter affection as opposed to predominantly white matter affection in postvaccinial demyelination.

A careful search should be made for the skin lesions of dengue, chikungunya, herpes zoster and hand foot and mouth disease. HHV-6 normally causes roseola. Hypertension in the child with altered sensorium would open up another set of diagnoses to pursue. The investigations should be tailored according to the patient's clinical history and presentation.

DIFFERENTIAL DIAGNOSIS

It is imperative to keep in mind that all the children with altered sensorium do not have viral encephalitis and that there are other treatable differential diagnoses. **Box 1** shows the possible differential diagnoses of viral encephalitis. Vasculitis involving the nervous system, brain tumors, demyelinating disease, autoimmune encephalitis, Hashimoto's encephalitis, metabolic and toxic encephalopathies and hypoxic brain damage should be considered, as the clinical picture warrants.

INVESTIGATIONS

Lumbar puncture (LP) should be done in all cases unless it is contraindicated. When LP is contraindicated due to raised

intracranial pressure (ICP), a CT scan should be performed as soon as possible with a plan to do a subsequent LP if the imaging does not reveal significant brain shift. In cases where LP is deferred, the case should be repeatedly reviewed and LP should be done when deemed safe.

Cerebrospinal fluid should be examined for cytology, biochemistry, Gram stain, Ziehl-Neelsen stain for acid-fast bacilli, bacterial culture, latex agglutination, polymerase chain reaction (PCR) for HSV-1 and -2, and IgM antibodies for JE and for Dengue virus (if suspected) **(Table 2)**. CSF should be checked for the total and differential cell count, Gram stain and acid-fast bacilli stain and subjected to culture and sensitivity testing. A sample should be retained for future investigational needs.

In 10%, the white cell count of the CSF will be normal. The CSF may show pleocytosis with raised protein in all encephalitis including rabies. Ideally viral culture from CSF, brain tissue, throat and stool specimens is necessary to identify the pathogen; but as these facilities are not commonly available, isolation of the viral nucleic acid from CSF is taken as diagnostic. CSF PCR tests are available for herpes viruses, EV and Parechovirus. The result of the PCR test for nucleic acid depends on the window during which the CSF was collected; with the highest yield during the first week and less during the second and subsequent weeks. Multiplex PCR is preferred over single PCR. Microarray for the viral DNA is expensive and not easily available.

If PCR of the CSF was not already done, or if CSF PCR is negative, CSF HSV specific IgG antibody testing should be done 2 weeks after onset of illness. When CSF PCR is negative, the serum has to be checked for IgM antibodies in two samples 2–3 weeks, apart for HSV-1 and -2, CMV, VZV, HHV-6, Enterovirus, Parvovirus, Adenovirus and Influenza A and B virus infection.

Antigen detection can be attempted from throat samples using immunofluorescence and enzyme linked immunosorbent assay; this will help detect HSV, VZV, influenza A and B and parainfluenza viruses. Virus type can be identified from cell cultures by electron microscopy.

If the patient has psychiatric symptoms, intractable seizures and new onset movement disorders with coma or if the patient has telltale evidence of an ongoing malignancy; antibodies to N-methyl-D-aspartate receptor and voltage-gated potassium channels should be checked. If the child with encephalitis has associated atypical pneumonia, *Mycoplasma* and *Chlamydia* serology and cold agglutinins in serum should be sought.

In cases of suspected AIDS virus encephalitis, HIV antibody test is done. In the immunocompromised, the CSF is subjected to India ink stain for *Cryptococcus* and Ziehl-Neelsen stain for *Mycobacterium tuberculosis*. Diagnostic investigations for immunocompromised patients with altered consciousness are given in **Box 2**. Throat swabs should be sent for H1N1 in case of clinical suspicion. In appropriate cases, throat and rectal swabs for enterovirus should be sent.

Table 2 The diagnostic modality of choice for each virus

Virus	Test of choice
Japanese encephalitis virus	Virus-specific IgM antibody in a single sample of CSF or serum, as detected by an IgM-capture ELISA specifically for Japanese encephalitis virus
Enteroviral encephalitis	Detection of EV genome by RT-PCR or an equally sensitive and specific nucleic acid amplification test (real time) in CSF. Isolation of virus from serum/stool/throat swab
Dengue viral encephalitis	Dengue virus-specific IgM antibody in a single sample of CSF as detected by an IgM-capture ELISA
HSV encephalitis	Detection of HSV DNA in CSF by PCR HSV specific antibody titers in serum and CSF
Mumps virus encephalitis	Detection of mumps virus RNA in CSF by PCR
Varicella zoster virus encephalitis	Detection of VZV DNA by PCR in CSF
Nipah virus	Detection of Nipah virus specific IgM antibodies in serum and CSF by IgM-capture ELISA PCR from CSF
Measles virus	Appearance of measles virus specific IgM antibody in the CSF
Chandipura virus	Detection of specific IgM antibodies in CSF by ELISA
Rabies virus	Corneal imprint smear, Nuchal biopsy, PCR for Rabies virus in CSF

Abbreviations: CSF, cerebrospinal fluid; ELISA, enzyme-linked immunosorbent assay; HSV, herpes simplex virus; PCR, polymerase chain reaction.

BOX 2 Investigations in immunocompromised patients with altered consciousness

- CSF PCR for HSV-1 and -2, VZV, enteroviruses, EBV, CMV, HHV-6 and -7, Adenovirus, Influenza and Parvovirus B_{19}
- CSF AFB staining and culture for Mycobacterium tuberculosis
- CSF culture for *Listeria monocytogenes*
- Blood culture
- Indian ink staining and cryptococcal antigen testing in CSF
- Antibody testing and if positive CSF PCR for *Toxoplasma gondii*
- Antibody testing of serum and if positive CSF for syphilis

Abbreviations: CMV, cytomegalovirus; EBV, Epstein-Barr virus; HHV, human herpes virus; VZV, varicella zoster virus.

Magnetic Resonance Imaging

Magnetic resonance imaging (including diffusion weighted imaging should be done in all patients, ideally within 24 hours if not within 48 hours). **Table 3** lists the MRI changes that act as pointers to the etiologic agent. Magnetic resonance spectroscopy, positron emission tomography and single-photon emission computed tomography are not indicated in suspected viral encephalitis.

Electroencephalography

Electroencephalography has limited utility in the evaluation of a child with acute viral encephalitis; especially with the recognition that periodic lateralized epileptiform discharges (PLEDS) are not diagnostic or exclusive to viral encephalitis. PLEDS are sharp waves or slow sharp waves that are seen recurring every 1–4 sec. However, it should be kept in mind that an EEG would be valuable in the evaluation; especially to pick-up nonconvulsive status that needs management, to pick-up a metabolic encephalopathy misdiagnosed as viral encephalitis and to exclude psychiatric causes of altered sensorium. EEG may show focal slowing or spiking; diffuse slowing follows, with a temporal predominance.

Stereotactic Brain Biopsy

Stereotactic brain biopsy may be considered in cases where no diagnosis has been reached and if the patient is deteriorating. If there is no focal lesion, the biopsy is taken from the nondominant frontal lobe. An experienced neurosurgeon and an experienced histopathologist are prerequisites for a brain biopsy. Characteristic owl-eyed inclusions are described in the cytoplasm of neurons in CMV encephalitis. Nuchal pad biopsy is the standard procedure in suspected rabies.

When the etiology is not clear, other microbiological investigations must be obtained. These are also required in epidemic situations, where the etiology has not been established. The local health authorities must be informed, and a microbiologist should be consulted when taking the samples. These samples include urine, throat swab, nasopharyngeal aspirate, serum (acute, and convalescent after 2 weeks) and swab from vesicles or rash, if present.

Table 3 MRI changes that could point to the etiologic agent in children with viral encephalitis

Region showing changes	Possible etiology
• Frontotemporal hyperintensities/significant edema and hemorrhage in the temporal lobes	HSV encephalitis
• Hippocampal	Limbic encephalitis due to VGKC antibodies
• Mixed intensity or hypointense lesions on T1WI and hyperintense or mixed intensity lesions on T2WI predominantly in the thalami, but also in the basal ganglia, brainstem, cerebellum, and cortical areas	Some arboviral encephalitis like Japanese B encephalitis
• Corpus callosum	H1N1 virus
• Diffuse excessive high-signal intensity and multiple punctate lesions in the white matter of periventricular region	Parechovirus, Nipah virus
• Hyperintense lesions on T2WI located within the brainstem (midbrain, pons and medulla) and dentate nuclei of the cerebellum. High-signal lesions can also be found in the anterior horn cells of spinal cord in patients with acute flaccid paralysis	Enterovirus 71
• Abnormalities in deep gray matter and brainstem (50%); white matter lesions mimicking demyelination	West Nile virus
• Symmetrical thalamic and basal ganglia changes	Rabies virus

Abbreviations: HSV, herpes simplex virus; VGKC, voltage-gated potassium channels.

MANAGEMENT

Every case of suspected viral encephalitis should be notified to the appropriate government agency to initiate case surveillance and the diagnostic process. Supportive care assumes great importance in the management of viral encephalitis with immediate attention to the airway, breathing and circulation. Hyperthermia and hypothermia should be corrected. Management of raised ICP when present with head elevation to 15–30°, use of intravenous mannitol, diuretics and controlled hyperventilation are part of the successful management. Euglycemia and electrolyte balance should be maintained. Seizures should be managed with timely recognition and treatment of nonconvulsive seizures. Ventilatory support, oxygenation and management of shock and syndrome of inappropriate antidiuretic hormone secretion should be instituted whenever necessary.

In areas endemic for malaria, empirical treatment for the same is started until a definite other diagnosis is established or malaria is ruled out. Empirical treatment for bacterial meningitis should be instituted in all cases. Doxycycline should also be initiated if the chances for a rickettsial or ehrlichial infection are high. Intravenous macrolides are included in the regime if there is suspicion of *Mycoplasma pneumoniae* encephalitis.

Empirical treatment with intravenous acyclovir (10 mg/kg three times daily or) 500 mg/m^2 8 hourly should be started if the initial CSF and/or imaging findings suggest viral encephalitis, or within 6 hours of admission if viral encephalitis cannot be ruled out with the available investigations and the patient shows no signs of recovery. Once the diagnosis of HSV encephalitis is proved, intravenous acyclovir treatment should be continued for 14–21 days. A repeat LP should be done at 21 days to confirm that the CSF is negative for HSV by PCR; if the CSF is still positive, acyclovir should be continued intravenously and PCR repeated until it is negative.

In patients who are HSV PCR negative, acyclovir can be stopped in immunocompetent patients, if (1) an alternative diagnosis has been made, (2) If HSV PCR in the CSF is negative on two occasions 24–48 hours apart, and MRI is not characteristic for HSV encephalitis, (3) HSV PCR in the CSF is negative once greater than 72 hours after neurological symptom onset, with unaltered consciousness, normal MRI (performed >72 hours after symptom onset), and a CSF white cell count of less than 5/mm^3.

Corticosteroids do not have a role in the treatment of viral encephalitis. Acyclovir 10–15 mg/kg three times daily for 3 weeks intravenously is recommended, with or without a short course of steroids for VZV encephalitis. No specific treatment is needed for cerebellitis due to VZV.

Ganciclovir (5 mg/kg intravenously twice daily) with foscarnet (60 mg/kg every 8 hours or 90 mg/kg intravenously every 12 hours) is recommended as initial therapy in CMV encephalitis; followed by ganciclovir (5 mg/kg/day) or foscarnet (60–120 mg/kg/day) for 3 weeks and 6 weeks for immunosuppressed patients. Oseltamivir is indicated in influenza virus encephalitis. Ribavirin has been used with success in acute measles virus encephalitis. There is experimental evidence of benefit of minocycline in JE.

PROGNOSIS

In general, prognosis is poorer in infants younger than 1 year. Rabies encephalitis is progressive and fatal, and therapy is largely palliative. The mortality rate in the case of measles encephalitis is between 10% and 20%, while sequelae are observed in 20–40% of patients who recover. Untreated, HSE is fatal in 70%. 30% die at 3 months with treatment. With acyclovir treatment less than half survive with no sequelae. Only 2.5% regain absolutely normal brain function. The good prognostic features include, short duration illness, and better sensorium when treatment was initiated. Even with early treatment, nearly two-thirds of the survivors may have significant neurologic sequelae. In animal models, seizures were associated with long-term mortality and, therefore, seizure control is emphasized in the management. Children who were

afflicted with encephalitis due to any virus could end up with a postencephalitic syndrome consisting of behavioral abnormalities, cognitive impairment and seizures.

REHABILITATION

Prompt recognition and management of respiratory infection, ventilator-associated pneumonia and urinary tract infection is necessary for recovery. Nutrition of the child should be supervised; the feeding tube, urinary catheter and tracheostomy should be tended carefully. The posture of the patient should be optimum to prevent contractures. Sessions with the psychologist, physiotherapist, occupational and speech therapist should be begun early.

PREVENTION

Japanese B encephalitis is the leading form of viral encephalitis in Asia, with a high mortality especially in children. Incomplete surveillance in many affected areas gives a false idea about the mortality. The WHO has, therefore, given priority for the prevention of JE and has initiated JE surveillance. Syndromic surveillance is undertaken for JE. In order to ensure that no case is missed, it is mandatory to report cases of acute encephalitic syndrome. Details are available in the chapter on *Japanese Encephalitis* in Section 31.

IN A NUTSHELL

1. Children with suspected viral encephalitis are often inadequately investigated and managed.
2. MRI or CT is a mandatory part of the diagnostic armamentarium in patients with encephalitis. PCR testing for the etiologic agent should be attempted. In doubtful cases, the stored serum and CSF samples should be available for serological testing.
3. Supportive therapy is still the mainstay.
4. Treatable differential diagnoses should always be considered during the evaluation of a patient with acute encephalitis syndrome.
5. Acyclovir should be given empirically to all suspected encephalitis. If bacterial meningitis cannot be ruled out or until it is ruled out, patient should receive treatment for pyogenic meningitis. In case of suspicion of rickettsial or ehrlichial infection, doxycycline should be given.
6. Once an etiologic agent of encephalitis is identified, antimicrobial therapy should be targeted to that infectious agent, or therapy should be discontinued if treatment directed against the etiologic agent is not available.

Chapter 42.18
Neurocysticercosis
Pratibha Singhi

Neurocysticercosis (NCC) is a parasitic infection of human brain caused by encysted larvae—cysticercus of the pork tapeworm *Taenia solium*. According to a recent meta-analysis epilepsy is associated with NCC in over a quarter of patients in endemic regions. Pediatricians in developing countries must have a high index of suspicion and should be aware of the varied manifestation of NCC as early diagnosis and treatment is highly rewarding.

EPIDEMIOLOGY

Approximately half a billion population worldwide is estimated to have cysticercosis. NCC is endemic in Southeast Asia, Latin America and sub-Saharan Africa, especially in the pig-rearing or pork-eating economically deprived communities. Global prevalence is difficult to assess as blood investigations are often noncontributory and neuroimaging is required to establish the diagnosis. A population-based study from Mexico, in 154 apparently asymptomatic residents using head CT scan for detection of NCC, reported a prevalence of 9.1%. In children (0–19 years), the estimated prevalence was 13.2%. In rural parts of North India, 25% cases with seizures were found to have an active NCC and another 10% a calcified granuloma. NCC contributes to a third of epilepsy cases in Latin America and 30–50% of acquired epilepsy cases in sub-Saharan Africa. Approximately 50% of children with focal seizures have been shown to have NCC in hospital-based studies from Peru and North India. The high prevalence of NCC in the poorest of poor leads to large economic losses in the already resource constrained developing world. Global spread of the disease has occurred with frequent international travel. Cysticercosis is now increasingly being reported from the developed world. Around 1,320–5,050 new cases of NCC occur every year in USA.

LIFE CYCLE OF *TAENIA SOLIUM*

Humans are the definitive host of adult *T. solium*. They acquire it by ingesting undercooked pork containing cysticerci. Once ingested, the cysts release larvae that attach to intestinal mucosa via their scolices and mature into adult worms. The adult female worm releases proglottids (segments) heavily laden with eggs that are passed in the stool of the carrier human. These eggs are later ingested by pigs grazing on soil contaminated by human excreta. The eggs release larvae in the pig intestine to form larvae that traverse the intestinal mucosa and spread through the blood stream to the pigs' muscles to form cysts; the cycle of *T. solium* is thus completed. Rate of transmission is high in rural communities where pigs roam free and open defecation is rampant.

Neurocysticercosis is caused by accidental human ingestion of *T. solium* eggs shed in stool of human tapeworm carriers. After entering the human gut, *T. solium* embryos (oncospheres) hatch in the small intestine and the larvae invade the bowel mucosa and disseminate hematogenously to brain, liver, striated muscle, subcutaneous tissue and eyes. They lodge at these sites and within 3 weeks to 2 months form tissue cysticerci which are fluid-filled membranous cysts with invaginated scolex. Cysticerci that reach the brain cause neurocysticercosis.

It is a common misconception that cysticercosis occurs because of eating pork. Pork ingestion leads to exposure to *T. solium* larvae which mature into adult tapeworms and cause taeniasis and not cysticercosis. Cysticercosis is transmitted through food contaminated with *T. solium* eggs either through food handlers who are carriers or through contaminated soil. An asymptomatic household tapeworm carrier is the most common source of infective eggs.

PATHOGENESIS

Within the brain, cysticerci are mostly located at the gray-white matter interface. These cysts may survive for prolonged periods without evoking host immune responses due to a number of protective mechanisms. Experimental models suggest that the live parasite releases a variety of substances such as taeniaestatin, glycoconjugates, paramyosin and secretory proteases which suppress the host immune reaction against the foreign cyst. The favorable environment withers and an inflammatory response is generated once the parasite is dead. It has been suggested that downregulation of cytokines through alternately activated macrophages may be another immune protective mechanism. The host immune attack causes cyst lysis and appearance of edema that is seen as mass effect and contrast enhancement on neuroimaging. In most cases, previously asymptomatic cysts become symptomatic at this stage of active inflammation and result in myriad forms of neurological signs and symptoms depending on their location, especially seizures, headache, and vomiting.

The brain parenchymal cyst evolves through four stages. The cyst characteristics and radiological appearance is provided in **Table 1**. Ultimately, the cysts either resolve or get transformed into a calcified granuloma. When calcification occurs, recurrent seizures may occur due to unclear pathogenetic mechanisms. Matrix metalloproteinases have been implicated in the pathogenesis of seizures in calcified lesions.

CLINICAL FEATURES

Neurocysticercosis is a disease with pleomorphic presentation. Its spectrum ranges from being asymptomatic to recurrent seizures and acute hydrocephalus. The clinical syndrome depends primarily upon the stage (viable/degenerating), location, size and number of cysts within the brain. Largely, NCC has two forms namely parenchymal and extraparenchymal. Classically, the parenchymal form is commoner and presents with seizures in children in contrast to the rarer extraparenchymal form that usually presents with acutely raised intracranial pressure (ICP). Major differences between the two forms are highlighted in **Table 2**. Pediatricians, however, must remember that the two forms may simultaneously or sequentially present in a single patient. Also, all stages of cysticercal cysts from vesicular to calcified granuloma may be seen in the same patient simultaneously.

Parenchymal Neurocysticercosis

This is the most common form of NCC in children as well as adults. The clinical feature depends upon whether a single or multiple cysts exist in the brain parenchyma. A single ring-enhancing lesion on contrast-enhanced CT scan of head **(Fig. 1)** is the most common finding in Southeast Asian countries. Clinical studies from endemic regions suggest that most of the parenchymal cysts are asymptomatic or are either found incidentally or are never diagnosed. Children may remain asymptomatic for several months or years until they present with an episode of afebrile seizure. In a series of 500 patients from our center, 95% had seizure as a presenting complaint. Seizures are short-lasting (less than 5 minutes) and are mostly focal (84–87%) usually complex partial seizures. Generally, a single seizure is seen. Clustering of seizures is uncommon but may occur in the initial 72 hours in up to 6% cases. Various other neurological signs and symptoms in descending order of frequency are presented in **Table 3**. Studies

Table 1 Stages of development of neurocysticercal cyst

Stages	Characteristics	Radiological features
Vesicular stage (Viable)	Live cyst filled with clear fluid, has a thin semitransparent wall, with an eccentric opaque 4–5 mm scolex. There is no evident inflammation around it and it is usually asymptomatic.	CSF density/intensity cyst with no enhancement. T1 hyperintense scolex may be visible. Wall is isodense to brain parenchyma.
Colloidal vesicular stage (Active)	Degenerating, an inflammatory response is elicited, the larva undergoes hyaline degeneration and the clear cyst fluid is replaced with opaque gelatinous material.	Cyst fluid turns turbid. *CT scan:* Hyperdense to CSF *MRI T1:* Hyperintense to CSF Cyst wall thickened and enhancing Surrounding edema present Scolex visible as an eccentric focus.
Granular nodular stage (Inactive)	Cyst contracts and the walls are replaced by focal lymphoid nodules and necrosis.	Cyst wall retracts. Edema decreases. Enhancement persists but is less marked.
Nodular calcified stage (Inactive)	The cyst transforms into a disk or nodular calcified lesion.	End-stage calcified cyst No enhancement No edema Signal drop out on T2 MRI sequences

Table 2 Differences between parenchymal and extraparenchymal neurocysticercosis (NCC)

Characteristics	Parenchymal NCC	Extraparenchymal NCC
Appearance	Small, cysts (5–20 mm). All 4 stages may be seen	Large, lobulated cysts adapting according to site of lodgment
Scolex	Easily visualized	Difficult to visualize
Clinical presentation	Seizures	Raised intracranial pressure, hydrocephalus
Imaging technique for diagnosis	CECT/CE-MRI brain	3D-CISS/FIESTA MRI sequences
Treatment	Antihelminthic therapy	Multiple course of antihelminthic therapy and surgical excision
Prognosis	Good	Poor
Figure 1 Contrast-enhanced computed tomography head shows single enhancing lesion with eccentric scolex and perilesional edema

Table 3 Frequency of clinical features in parenchymal neurocysticercosis in children

Features	Percentage	Features	Percentage
Seizures	70–95	Papilledema	2–7
Nausea and vomiting	25–31	Motor neurodeficit	4–6
Headache	25–28	Cranial nerve palsy	0–1
Status epilepticus	2–32		

Adapted from Baranwal et al, 1998; Singhi et al, 2000; Talukdar et al, 2002

have shown some regional differences in the clinical presentation of NCC across the world. In India and other Asian countries, NCC almost always is symptomatic in the degenerating stage in contrast to a sizeable proportion of cases from Latin America where viable vesicular cysts are seen in symptomatic patients.

In children with large number of parenchymal cysts, an intense immune reaction develops resulting in diffuse brain edema and a clinical scenario termed cysticercal encephalitis. The patients present with altered sensorium, headache, seizures, status epilepticus, visual blurring or other signs of raised ICP. Cysticercal encephalitis is associated with poorer prognosis when compared to single parenchymal NCC.

Other rare presentations of NCC include isolated cranial nerve palsy, ptosis, intranuclear ophthalmoplegia and dorsal midbrain syndrome due to brainstem NCC, movement disorder (basal ganglia NCC), meningitis, behavioral and psychiatric manifestations.

Extraparenchymal Neurocysticercosis

Extraparenchymal NCC may result from intraventricular or subarachnoid cysticerci. Rarely, it may present as spinal or ocular disease.

Intraventricular Neurocysticercosis

Cysticerci may be present inside the ventricular system as free-floating cysts or attached to the ependyma. The child becomes

symptomatic whenever the cerebrospinal fluid (CSF) outflow is blocked due to an enlarging cyst or obstruction of ventricular foramina. The most preferred locations within the ventricular system are fourth ventricle (53%), third ventricle (27%), lateral ventricles (11%) and aqueduct (9%). Children may present with acute raised ICP or obstructive hydrocephalus. The obstruction in CSF flow may occur abruptly or gradually, intermittently or permanently. Rarely, mobile cysts may cause intermittent obstruction and lead to episodic loss of consciousness with head movement—Brun's syndrome.

Subarachnoid Neurocysticercosis

Cysticerci may lodge in the subarachnoid spaces in the sylvian fissure and basal cisterns and induce inflammation giving rise to arachnoiditis often accompanied by hydrocephalus, meningitis or vasculitis. Cysts within the sylvian fissures may at times enlarge disproportionately without scolices and appear as a lobulated mass with *bunch of grapes* appearance called *racemose* NCC. These giant cysticerci may cause mass effect, hydrocephalus, secondary infarcts and focal neurological deficits.

Spinal Neurocysticercosis

Occurs rarely; signs and symptoms of spinal dysfunction may be seen such as radicular pain, paresthesias, sphincter disturbances and paraplegia when cysts lodge in the spinal subarachnoid space. Intracranial subarachnoid NCC is usually associated with spinal lesions.

Ocular Cysticercosis

Ocular cysticercosis is seen in 1–3% of cases. Cysts may reside in any part of the eyes including the subretinal space, vitreous humor, anterior chamber, conjunctiva and extraocular muscles, and cause symptoms accordingly.

APPROACH TO DIAGNOSIS

The signs and symptoms of NCC are nonspecific and, therefore, the mainstay of diagnosis is imaging. Combination of other factors such as epidemiology, symptomatology and serology may provide corroborative evidence. Diagnostic criteria based upon clinical, radiological, immunological and epidemiological data were proposed by Del Brutto in 2001 and later revised; however, they have not been validated in various parts of the world.

Neuroimaging

A reasonable clinical approach is to obtain a contrast-enhanced computed tomography (CECT) head in any child with suspected NCC. If CT is not contributory and the suspicion of NCC is high then a CE-MRI brain and serology should be considered. In most cases, CT is sufficient to establish a diagnosis except in certain cases such as intraventricular or subarachnoid NCC, cysticercal encephalitis, brainstem NCC or when scolex is not identified.

Parenchymal Neurocysticercosis

The characteristic CT finding in NCC is a small (< 20 mm), low-density smooth-walled lesion with ring or disk enhancement and an eccentric scolex appearing as a bright central dot. In the Indian subcontinent most cases present as a single enhancing lesion (SEL) representing a degenerating cyst. However, a significant proportion of cases from Latin America and Africa have multiple viable cysts at presentation. A mild-to-moderate perilesional edema is often seen **(Fig. 1)**. Infrequently, numerous cysts of varying stages are seen studded over the brain parenchyma giving rise to a *starry sky appearance* which is a hallmark of NCC. Calcified cysts, best seen on CT, are small 2–4 mm in diameter (range 1–10 mm), solid and nodular. Presence of multiple parenchymal calcifications on CT is highly suggestive of NCC. The CT findings of various stages of parenchymal cysts are tabulated in **Table 1**.

Magnetic resonance imaging (MRI) of brain is superior to CT in detecting NCC, visualizing scolex and identifying extraparenchymal cysts. The scolex is best seen on proton density-weighted images as a small 2–4 mm nodule within the cyst cavity that is isointense to hyperintense relative to white matter. The first indication of cyst degeneration is the presence of enhancement. As the degeneration progresses, the cyst content changes from hyperintense to hypointense on T2 images and the cyst wall changes from hypointense to hyperintense appearance.

Extraparenchymal Neurocysticercosis

Computed tomography (CT) may not be able to identify small intraventricular lesions; however, leptomeningeal enhancement and large racemose NCC can be identified as cystic hypodense lesions in the subarachnoid space in the sylvian fissures or cerebellopontine angle. High-resolution T2 MR sequences such as three dimensional-constructive interference in steady state (3D-CISS) and fast imaging employing steady state acquisition (FIESTA) are superior in identifying scolex in the intraventricular/subarachnoid cysts.

Serology

Serology acts an adjunctive modality to imaging in the diagnosis of NCC. Number of serological tests detecting anticysticercal antibody or cysticercal antigen in serum and CSF have been developed. In general antibody detecting techniques are preferred over assays employing unfractionated antigens. The enzyme-linked immunoelectrotransfer blot developed by CDC is highly specific (83–100%) and 100% sensitive for multiple and extraparenchymal NCC. It utilizes affinity-purified glycoprotein antigen from *T. solium* cysticerci (Tsang et al., 1989). However, like other serological tests, it lacks sensitivity for low disease burden—single NCC or calcified NCC. A comparative study from our center showed that antigen detecting ELISA and antibody detecting dot-blot assays are more sensitive for multiple lesions (100%) when compared to single lesion (87%). Serological tests do not differentiate between neural and extraneural cysticerci and therefore, false positive results can occur in endemic regions. Various newer assays based on excretory secretory antigens, synthetic polypeptides and *nano bodies* are under evaluation. A positive test result supports the diagnosis but a negative test does not exclude the diagnosis.

Cerebrospinal Fluid

Lumbar puncture is not required for the diagnosis of NCC. In parenchymal NCC, the CSF is normal. In the setting of cysticercal meningitis, encephalitis and arachnoiditis, CSF may show elevated protein, low sugars and pleocytosis. Cells may be predominantly lymphocytes, neutrophils or eosinophils. Eosinophilic meningitis usually suggests a parasitic etiology and therefore may help in differentiating from other nonparasitic causes of chronic meningitis such as tuberculosis.

Other Investigations

Peripheral eosinophilia may be seen occasionally. Stool examination may detect taeniasis but is nonconclusive for cysticercosis. Biopsy of subcutaneous nodules may detect a viable parasite and muscle radiographs may detect calcified extraneural cysticerci. Such tests are rarely required in clinical settings.

DIFFERENTIAL DIAGNOSIS

In endemic countries, NCC is generally the most common acquired cause of first episode of afebrile focal seizure in children and should be actively excluded by neuroimaging. Depending on the clinical scenario or radiological findings other differentials have to be considered. Most of endemic regions for NCC are also endemic for tuberculosis. Small tuberculoma may also present as SELs. Visualization of scolex within the cyst cavity is a pathognomic radiological finding of NCC. If the scolex cannot be identified, tuberculoma needs to be considered. Tuberculosis must always be excluded in such cases with clinical history, examination and laboratory investigations such as Mantoux, chest X-ray, and gastric aspirate analysis for acid fast bacilli. There are a number of ways of differentiating between these two most common causes of SEL **(Table 4)** but it may not always be possible. Newer MRI techniques such as CISS and FIESTA are superior to spin echo MRI in identifying scolex. Lactate peak and choline/creatine ratio greater than 1 on proton magnetic resonance spectroscopy may favor a diagnosis of tuberculoma. Other differentials of SEL are microabscesses, toxoplasmosis, mycotic granulomas and primary or metastatic tumors. Rarely, focal demyelinating lesions may also show ring enhancement. Parenchymal calcifications may be seen in intrauterine infections, metabolic disorders and vascular malformations.

Cysticercal meningitis/encephalitis has to be differentiated from other possible etiologies of chronic meningitis such as tubercular and fungal meningitis. Presence of associated parenchymal cysts and eosinophilia may favor NCC over other nonparasitic etiologies. Intraventricular cysts have to be differentiated from colloid, arachnoid, and epidermoid cysts.

MANAGEMENT

Treatment of NCC is a two-pronged approach, namely:
1. Symptomatic therapy with analgesics, anti-inflammatory agents and antiepileptics
2. Definitive cure with antihelminthic therapy for parenchymal lesions and surgical excision for extraparenchymal lesions.

Symptomatic Treatment

Symptomatic therapy is guided by the clinical presentation, location of cysts and presence of raised ICP. Children presenting with status epilepticus, altered sensorium or signs and symptoms of acutely raised ICP may require emergency admission and hospitalized care. Children with first episode of seizure, infrequent seizures or headache can be managed at home.

Table 4 Differences between parenchymal neurocysticercosis and tuberculoma

Features	Neurocysticercosis	Tuberculoma
Size	< 20 mm	> 20 mm
Site	Supratentorial (gray-white junction)	*Infratentorial
Perilesional edema	Mild	Moderate/severe
Midline shift	Less common	More common
Cyst wall	Thin, smooth	Thick, irregular, lobulated
Eccentric nodule (scolex)	Present	Absent
Raised intracranial pressure	Uncommon	Common
Progressive focal deficit	Uncommon	Common

*Usually

Antiepileptics

As seizures are the most common presenting feature, early initiation of appropriate antiepileptic drug (AED) is of utmost importance. No trial has compared the efficacy of various antiepileptics for seizures secondary to NCC. However, most cases respond well to standard doses of carbamazepine or phenytoin monotherapy. The duration of AED therapy has often been debated. Seizure recurrence correlated with abnormal CT scan (persistent or calcified lesion) and abnormal electroencephalogram (EEG) at the time of AED withdrawal. A practical approach may be to withdraw AED after one-year seizure-free interval in cases where resolution of lesion and a normal EEG has been documented; in other cases, AED therapy may be extended for one more year.

Corticosteroids

Steroids are required in NCC: (1) to reduce the surrounding perilesional vasogenic edema and provide symptomatic relief; (2) to prevent the presumed triggering of intense inflammatory reaction after initiation of antihelminthic treatment due to lysis and degeneration of cysts. A short course of oral prednisolone at 1–2 mg/kg/day for 5–7 days is usually used. A slightly prolonged course may be required in children with multiple NCC or when significant perilesional edema is present. In cases with acute raised ICP intravenous dexamethasone may be considered.

Definitive Therapy

Antihelminthic Therapy

The definitive therapy for parenchymal and extraparenchymal NCC differs. Until recently, the role of antihelminthic therapy for parenchymal NCC has been debated. A double-blind placebo-controlled trial in 63 children with single NCC showed significantly increased and faster disappearance of lesion within 1 month of albendazole therapy compared to placebo. Randomized controlled trials and meta-analysis of treatment studies have now shown an early resolution and less chances of seizure recurrence in children and adults treated with antihelminthic therapy when compared to no treatment. A recent meta-analysis concluded that antihelminthic therapy was associated with increased rate of seizure control and resolution of lesion in cases with single lesion. The American Academy of Neurology recommends albendazole and corticosteroids for treatment of parenchymal NCC in both children and adults. However, it is worth stressing that initiation of cysticidal therapy is not an urgency and it is preferable to wait until the child is stable before initiating antiparasitic drugs.

Albendazole/Praziquantel

Albendazole and praziquantel are the cysticidal drugs used for NCC. Albendazole is preferred over praziquantel as: (1) It has better penetration in subarachnoid space and good tolerability. (2) Concomitant use of steroids increases bioavailability of albendazole and decreases that of praziquantel. (3) Antiepileptic drugs such as phenytoin and carbamazepine decrease the bioavailability of praziquantel but do not alter that of albendazole.

In uncomplicated parenchymal neurocysticercosis, albendazole at 15 mg/kg/day in three divided doses is used for 8 days to 4 weeks. Some studies have found that a 1-week therapy with albendazole was equally efficacious as a four-week regimen for 1–3 parenchymal cysts. Multiple lesions require a four-week course. Praziquantel is used at a dose of 50 mg/kg/day in two divided doses to be taken with meals for 2 weeks.

After a single course of cysticidal therapy about 60–70% of cysts die. A repeat course of cysticidal therapy may be used in cases with

persistent lesions. Combination therapy using both praziquantel and albendazole has been found to be safe and promising. Increased levels of an intermediate sulfoxide metabolite of albendazole when a combination therapy is instituted contribute to heightened cysticidal activity.

In cases with multiple NCC with extensive edema antihelminthic therapy may initiate degeneration of all the cysts simultaneously evoking inflammation at multiple sites within the brain leading to worsening of edema. Therefore, such cases need to be treated with caution. Cysticidal therapy is contraindicated in disseminated NCC until edema is taken care of. It is also contraindicated in ocular NCC because of the risk of triggering inflammation within the eye and consequent visual loss. Once the lesions are calcified, cysticidal therapy is of no use. Cysticercal encephalitis is primarily treated with corticosteroids alongwith other symptomatic treatment for raised ICP.

Surgery

Surgical excision with endoscopic removal or open surgery with or without shunt placement is mainstay of treatment for intraventricular and subarachnoid NCC. Endoscopic cyst removal is employed for nonadherent easily accessible cysts. No consensus guideline for management of extraparenchymal cysts exists; however, most experts recommend early surgical removal of cyst whenever feasible. The most important advantage of surgical excision is immediate removal of obstruction, reduced chances of future hydrocephalus, decreased chances of shunt requirement and avoiding long-term corticosteroid therapy. In resource limited settings where neurosurgical expertise is lacking an urgent shunt placement to relieve hydrocephalus with prolonged corticosteroids and antihelminthic therapy may be used. Use of two courses of albendazole at 15 mg/kg/day for one month each, one month apart with corticosteroids has been found effective in treating intraventricular cysts with cyst resolution noted within three months of treatment.

OUTCOME

Parenchymal disease has a much better outcome compared to extraparenchymal forms and single lesion has a much better prognosis compared to multiple lesions. Single lesions usually disappear within 6 months in 60% cases. Radiological resolution must therefore be documented by repeat imaging within 3–6 months. Persisting lesions may require a repeat course of antihelminthic therapy. Seizure recurrence occurs in 10–20% cases with single NCC. Multiple NCC and calcified lesions are associated with frequent seizures and may require prolonged course of antiepileptics.

PREVENTIVE STRATEGIES

Preventive strategies aimed at blocking the transmission of tapeworm infections and eggs to humans are required to curtail the prevalence of NCC.

Transmission of Tapeworm Infections to Humans

This can be halted by prevention of human exposure to infected pork meat and by preventing infections in pigs to curb the perpetuation of infection. Human exposure can be curtailed by: (a) proper inspection of pork meat for visible cysticerci; (b) adequate cooking of pork to destroy cysticerci. Infection in pigs can be prevented by confining pigs and restricting their exposure

to human waste. Adequate large scale sanitation methods with appropriate sewage disposal systems and avoiding open defecation are vital. Community level interventions, when properly instituted have found to decrease the incidence of epilepsy in highly endemic regions. Mass community antihelminthic therapy is advocated as a measure to decrease the prevalence of NCC. The drug of choice is a single dose of niclosamide (1–1.5 g) in children or praziquantel 10 mg/kg single dose.

Vaccination of pigs with newer vaccines such as TSOL18 along with oxfendazole treatment has been found to be effective. Such programs at large scale are however not feasible in many resource constrained hyperendemic regions.

Transmission of Eggs between Humans

As transmission of eggs from asymptomatic carrier humans plays a major role in disease spread, blocking it by simple approaches such as community education regarding disease transmission, personal hygiene, hand washing and thorough washing of vegetables and fruits before cooking may be beneficial.

IN A NUTSHELL

1. Neurocysticercosis caused by *T. solium* larvae is one of the most common parasitic infections of the human brain and a common cause of acquired epilepsy in children in endemic regions.
2. Neurocysticercosis is endemic in Southeast Asia, Latin America and sub-Saharan Africa, especially in the pig-rearing or pork-eating economically deprived communities. However, it is seen worldwide.
3. Transmission of NCC is via feco-oral route usually through food handlers who are tapeworm carriers. It is perpetuated by infected pigs. Pork-eating causes taeniasis, not cysticercosis.
4. Classically, the commoner parenchymal form presents with seizures and the rarer extraparenchymal form causes raised ICP and hydrocephalus. However, the presentation can be pleomorphic.
5. Brain imaging with CT/MRI usually shows a small SEL, but multiple lesions may be seen. Identification of scolex is diagnostic of NCC.
6. Positive serologic test adds to the diagnosis of NCC; a negative test does not exclude it.
7. Cysticidal therapy is associated with increased rate of resolution of lesions and perhaps better seizure control. A short course albendazole and corticosteroids therapy is now recommended for treatment of parenchymal NCC in both children and adults.
8. Cysticidal therapy is contraindicated in disseminated and ocular NCC and has no role in calcified lesions.
9. Surgical removal of cyst with or without shunt placement is the recommended modality of therapy for intraventricular or subarachnoid NCC.
10. Neurocysticercosis is preventable—sanitation, hygiene and proper animal husbandry are essential.

Chapter 42.19
Brain Abscess
Prashant Jauhari, Jitendra Kumar Sahu

Brain abscess is an intracranial suppurative pathology with high morbidity and mortality. It is a dynamic focal infection within the brain parenchyma, which begins as a localized area of cerebritis and evolves into a collection of pus within a well-vascularized capsule. Once formed, brain abscess can lead to permanent neurological sequelae via destruction, infarction, compression or herniation. Most commonly brain abscesses are pyogenic in nature and a significant proportion has a polymicrobial etiology. Early identification, judicious parenteral antibiotic therapy, and prompt and aggressive neurosurgical intervention are the most important components of management of such children.

EPIDEMIOLOGY

Brain abscess is the most common type of intracranial pus collection. It is prevalent worldwide. A decline in incidence has been noticed in the developed world as opposed to high incidence in economically deprived regions due to better medical facilities, better hygiene and decreased incidence of infections. Hospital-based studies from India report an average incidence of 8–15 cases/year compared with 1.5 cases/year reported from USA. Brain abscesses account for 8% of intracranial masses in developing countries and 1–2% in the developed world. Pediatric cases constitute almost 25–42% of all brain abscess patients. Congenital heart diseases have remained the most common predisposing factor. Recent epidemiological changes include a reduction in brain abscesses cases secondary to sinus and ear infections in the western world, increased detection of neonatal abscesses and increased incidence of fungal abscesses in immunocompromised children.

PATHOGENESIS/PATHOPHYSIOLOGY

Brain is a well-protected organ which is inherently resistant to infection. Entry of pathogenic microorganisms is effectively blocked by the blood-brain barrier and that is why brain abscess is a rare consequence of bacteremia, which is common in infants and children. Once the integrity of blood-brain barrier is breached seeding of the organism in a devitalized area of brain or in a region with poor microcirculation within the parenchyma becomes the foremost step in formation of brain abscess.

Route of Infection

Spread of infection or inoculation into the brain occurs by three possible routes.
1. *Contiguous spread* (25–50%) involves spread of infection from pericranial non-neural contiguous focus such as the sinuses, middle ear, dental infection or inflamed meninges as a complication of meningitis. The valveless venous channels interconnecting the intracranial and sinus mucosal veins provide an alternative intracranial access to bacteria. Dental infections may ascend to the intracranial space via aberrant venous pathways or retrograde venous flow during yawning and mastication. Dental infections, ethmoid or frontal sinusitis usually spreads to the frontal lobe, and subacute or chronic otitis media or mastoiditis preferentially spreads to cerebellum in younger children and temporal lobe in older children.
2. *Hematogenous spread* (15–30%)—From a distant focus of infection such as heart [congenital cyanotic heart disease (CCHD), bacterial endocarditis], lungs (empyema), skin and intra-abdomen. Abscess site follows a distribution that reflects the cerebral arterial supply, most commonly that of the middle cerebral artery. Hematogenous spread can also occur by way of the veins that drain into the cavernous sinus, resulting in frontal lobe abscesses that are often correlated with infections of the facial tissues or ethmoidal sinuses.
3. *Direct inoculation* (8–15%)—Secondary to compound skull fractures, scalp wounds anterior cranial fossa or temporal bone fractures, chronic cerebrospinal fluid (CSF) fistula and neurosurgical procedures.

Brain abscess resulting from contagious spread is usually single, while multiple brain abscesses mostly result from hematogenous spread.

Stages of Abscess Formation

The natural evolution of brain abscess can be divided into four distinct stages **(Table 1)**. The abscess begins as a focal area of infection with surrounding edema and inflammation. Within a few days, central necrosis starts to occur which progresses outward and ultimately liquefies the affected area. Within weeks, this area gets walled off by a collagenous capsule formed by the accumulating fibroblasts limiting the spread. Within 3–4 weeks, a dense fibrous capsule is formed which is amenable for resection. Further with increasing pressure within the capsule microorganisms escape out and form daughter abscesses in the adjoining area **(Fig. 1)**. Animal studies have demonstrated that abscesses mostly occurred in the white matter or at the gray-white matter junction and gradually migrate to the ventricle. The abundant capillary beds at these sites facilitate frequent lodging of the bacteria and development of brain abscess. The capsule of the abscess is thickest toward the meninges and thinnest toward the ventricle and, therefore, increased chances of rupture within the ventricular system. Pediatric brain abscesses are supratentorial in 85%, infratentorial in 13% and combined location in 2% cases.

Predisposing Factors

The most common predisposing factors for brain abscess in childhood are cyanotic congenital heart diseases, sinus and otogenic infections and dental infections and procedures. Other

Table 1 Histological stages of brain abscess

Stages	Duration	Histological features
Stage I: Early cerebritis	1–3 days	Microglia and astrocyte activation, neutrophil accumulation, edema and tissue necrosis
Stage II: Late cerebritis	4–9 days	Macrophage and lymphocyte infiltration. Expansion of the cerebritis and formation of central necrotic focus
Stage III: Early capsulation	10–14 days	Formation of a ring enhancing dense collagenous and vascularized abscess capsule with peripheral gliosis and fibrosis
Stage IV: Late capsulation	Beyond 14 days	Thickening of abscess capsule. Focal suppuration completely walled off. Abscess amenable to excision within 3–4 weeks.
Figure 1 Axial T1-weighted MRI section with gadolinium in a 4-month-old infant shows presence of a large intracerebral abscess with budding daughter cysts. Associated vasogenic edema and midline shift could also be seen

Figure 2 CECT head of a 1-year-old girl with cyanotic congenital heart disease shows multiple pyogenic brain abscesses

risk factors identified are immunosuppression, neurosurgical procedures such as ventriculoperitoneal shunts, penetrating skull injury and comminuted fracture of the skull, and congenital lesions of the head and neck (dermal sinuses). Infreqently, brain abscess occurs as a complication of pyogenic meningitis. Occasional reports of brain abscess following aspiration of foreign bodies, esophageal endoscopy and ocular trauma exist in literature. In a significant proportion of children (14–25%), no identifiable predisposing factor is found (cryptogenic brain abscess).

Unoperated CCHD accounts for 25–46% of brain abscess cases in children. The incidence of brain abscess in children with CCHD is approximately 2%. Intracardiac right-to-left shunt bypasses the pulmonary circulation and therefore allows bacteria to gain direct entry into the cerebral circulation. In addition, polycythemia secondary to decreased arterial oxygenation and hyperviscosity cause a focal area of ischemia and necrosis that acts as a nidus for infection forming a cerebral abscess. However, this complication of CCHD rarely develops before 2 years of age, after which, the risk of abscess formation increases consistently till 12 years of age with a peak incidence between 4 and 7 years of age. The most common form of cyanotic congenital heart disease associated with brain abscess is tetralogy of Fallot (45%) **(Fig. 2)**. Other common CCHD associated with brain abscess are complete transposition of the great arteries and double outlet of right ventricle. An associated endocarditis is rare in these cases, although acute bacterial endocarditis in itself is an independent predisposing factor for brain abscess. A reverse blood flow across patent foramen ovale during valsalva may allow paradoxical septic emboli to reach the cerebral vasculature.

Otorhinogenic sepsis is another important risk factor for brain abscess in children and adolescents. In India, chronic suppurative otitis media constitutes up to 50% cases of brain abscess across all ages. Immunosuppression is recognized as a major predisposing factor for brain abscess. Infections with HIV, malignancy, iatrogenic immunosuppression with long-term steroid therapy, chemotherapeutic agents, and organ transplant patients have increased susceptibility for intracranial suppuration secondary to atypical or opportunistic organisms.

Brain abscess as a complication of meningitis is rare with meningitis constituting approximately 12–36% of overall brain abscess cases in childhood particularly in infants and toddlers. Meningitis may occur concomitantly during the incipient stages of abscess formation after an organism has seeded the brain parenchyma from a contiguous extracranial source. In such scenarios, meningitis is a consequence of brain abscess instead of the opposite being true. Neonates with meningitis due to atypical pathogens such as *Citrobacter* and *Enterobacter Sakazakii* have increased chances of developing brain abscess.
ETIOLOGY

In immunocompetent children, majority of abscess are bacterial in origin (50–60%). The most common microorganisms causing brain abscess in children worldwide are aerobic and anaerobic streptococci. **Table 2** mentions the other common pathogens identified in pediatric brain abscess. Polymicrobial etiology is seen in a third of cases. In at least 15–30% of childhood brain abscess, no etiological agent could be identified. **Table 3** provides the most common microorganism associated with brain abscess based on the predisposing source of infection. In immunocompromised children, atypical pathogens such as fungal organisms and mycobacterium are commonly seen.

CLINICAL FEATURES

The signs and symptoms of brain abscess are nonspecific at the onset. The classical triad of headache, fever and focal neurological signs is rare. Broadly, the clinical features results from any of the four clinical syndromes namely focal mass expansion, intracranial hypertension, diffuse destruction and focal neurological deficits.

Table 2 Usual pathogens associated with pediatric brain abscess

Microorganism	Percentage
Streptococcal species	60–70
Gram-negative anaerobic bacilli	20–40
Enterobacteriaceae	20–30
S. aureus	10–15
Fungi	1–5
Mycobacterium	4

Table 3 Source of infection, probable etiological agent and site of abscess

Source of infection	Probable pathogens	Site of brain abscess
Paranasal sinus	Viridans and anaerobic streptococci, *Haemophilus* sp., *Fusobacterium* sp., *Bacteroides* sp. (nonfragilis)	Frontal lobe
Otogenic	Gram-negative enteric bacilli, *Bacteroides* sp. (including *B. fragilis*), streptococci, *P. aeruginosa*	Temporal lobe cerebellum
Odontogenic	Steptococci, Gram-negative bacilli, *B. fragilis*	Frontal lobe
CCHD	Streptococci	Parietal/multiple
Endocarditis	*Viridans* streptococci, *S. aureus*	Parietal/multiple
Surgical procedures	*S. epidermidis, S. aureus, P. aeruginosa*	At operative site
Penetrating trauma	*S. aureus*, aerobic streptococci	At trauma site
Immunosuppression	*Nocardia*, fungi, *Mycobacterium*	Variable

Abbreviation: CCHD, congenital cyanotic heart disease

The symptom constellation depends upon several factors such as predisposing risk factor, age, size, site and number of abscess. A nonspecific headache is the most common symptom in older children and adolescent. In infants, irritability, excessive crying on handling and fussiness is the initial complaint followed by lethargy, fever, vomiting, bulging fontanel, frequent seizures and increase in head circumference.

Intracranial abscess is an exception to the general belief that pus collection is associated with high-grade fever. Fever may be present only in 50–80% and, therefore, its absence should not exclude the diagnosis. Similarly, focal deficits are seen in not more than half of the cases. The frequencies of various clinical symptoms are provided in **Table 4**.

As the abscess evolves, surrounding vasogenic edema increases and results in midline shift and worsening signs of raised intracranial pressure (ICP) and impending herniation. Sudden worsening of sensorium, high-grade fever, severe headache and meningismus may suggest rupture of abscess into the ventricular cavity. Depending upon the involved cerebral lobe specific dysfunction in brain function is observed **(Table 5)**. Frontal and parietal lobes are the two most common sites respectively. Brainstem abscess are very rare (< 2%). Pontine abscesses may compress aqueduct of Sylvius and cause obstructive hydrocephalus. Typical brainstem syndromes are generally not seen due to longitudinal rather than lateral spread of the abscess.

DIAGNOSIS

Mainstay of diagnosis is visualization of the abscess on imaging. Most of the laboratory investigations remain unremarkable.

Neuroimaging

Magnetic Resonance Imaging of Brain

Magnetic resonance imaging (MRI) of brain with gadolinium is the imaging modality of choice for diagnosing brain abscess. It is superior to computed tomography (CT) scan in identifying early stages of cerebritis, microabscesses, brainstem and cerebellar pus collections. MRI can also aid in identifying nearby sources of infection such as sinusitis or mastoiditis. On T1-weighted images, brain abscess appears as a hypointense lesion with ring enhancement on gadolinium administration. On T2-weighted images, it appears as a central hyperintense lesion encircled by a uniform hypointense capsule and surrounded by an irregular hyperintense area of perilesional edema.

Newer modalities of MRI imaging such as diffusion-weighted imaging (DWI) can further differentiate between brain abscess

Table 4 Clinical features of brain abscess

Clinical symptom	Percentage	Clinical symptom	Percentage
Headache	50–80%	Meningismus	25–50%
Fever	60–80%	Alteration of sensorium	30–50%
Vomiting	20–70%	Unconsciousness	10–20%
Focal deficits	35–50%	Hydrocephalus	6–17%
Seizures	20–25%	Papilledema	30–40%

Table 5 Clinical symptomatology of brain abscess based on specific cerebral region involved

Cerebral region	Clinical characteristics
Frontal lobe	Sinus/dental infection common; initially silent, drowsiness, personality change, seizures, appearance of primitive reflexes, hemiparesis
Parietal lobe	Hematogenous spread common; visual field defects inferior quadrantanopia to homonymous hemianopia Dominant hemisphere: Dysphasias; nondominant hemisphere: dyspraxia and spatial neglect
Temporal lobe	Associated otogenic infection common; dominant hemisphere: dysphasias; nondominant hemisphere: superior quadranopsia
Occipital lobe	Homonymous hemianopia; rupture into ventricle causing ventriculitis/ependymitis; septic thrombophlebitis of the transverse sinus
Cerebellum	Uncommon; appendicular and gait ataxias; eye movement abnormalities
Brainstem	Multiple cranial nerve palsies; obstructive hydrocephalus

and necrotic tumors. Proton MR spectroscopy is useful in differentiating between abscess, radiation necrosis other cystic lesions. Perfusion MRI with dynamic intravenous contrast injection studies can differentiate between these lesions by analyzing the vascularity of the lesion and blood flow. Thallium single-photon emission computed tomography and fluorine-18 fluorodeoxyglucose positron emission tomography have been effective in adults in differentiating brain abscess from tumor in doubtful cases. However, its role in pediatric cases has not been extensively studied. Radiological appearance of brain abscess on various MR sequences is tabulated in **Table 6**.

Computed Tomography of Head

Computed tomography is helpful in identifying the site, number and location of brain abscess in most cases and can be used for monitoring the progression of disease after initiation of antimicrobial therapy or surgical drainage. It can also detect other abnormalities such as subdural empyema, leptomeningeal enhancement, ventriculitis and hydrocephalus. The appearance of lesion depends upon the evolutionary stage of abscess. Initially during early cerebritis, it may appear as a low signal area with mass effect and may not show enhancement with contrast. In later phases, the typical finding is of a hypodense lesion with thin uniform ring enhancement on contrast-enhanced CT (CECT) imaging.

High-resolution cranial ultrasonography can be used in neonates and infants with open anterior fontanel for diagnosis of brain abscess and subdural empyema.

Cerebrospinal Fluid Analysis

Brain abscess is an exceptional central nervous system infection where lumbar puncture (LP) is contraindicated. Often, due to mass effect and vasogenic edema, the ICP is asymmetrically raised and LP may cause sudden herniation and collapse. Also in cases where LP is performed, it failed to aid in the diagnosis of brain abscess. One has to remember that unless brain abscess has ruptured into the ventricular system or concomitant meningitis exists, CSF analysis may be unremarkable. Most common CSF findings in brain abscess are mild mononuclear pleocytosis, mildly elevated protein and normal to slightly low sugars with sterile cultures. CSF culture is positive in less than 10% cases only. Once ventriculitis sets in secondary to rupture of abscess into the ventricles, CSF may show marked leukocytosis with 50,000–100,000 cells, significant

Table 6 Radiological appearance of brain abscess on MRI

MRI sequences	Appearance
T1 weighted	Central low intensity Peripheral low intensity (perilesional edema)
T1 weighted with gadolinium	Ring enhancement
T2 weighted/FLAIR	Central high intensity Peripheral high intensity (perilesional edema) Capsule appear as thin rim of intermediate to slightly low signal intensity
DWI	High DWI signal centrally Low signal on ADC
Perfusion MRI	Reduced relative cerebral blood volume
MRS	Elevated succinate and lactate peaks Choline: creatine and NAA peaks reduced

Abbreviations: FLAIR, fluid attenuated inversion recovery; DWI, diffusion-weighted imaging; ADC, apparent diffusion coefficient; NAA, n-acetyl aspartate; MRS, magnetic resonance spectroscopy

hypoglycorrhachia (CSF sugar < 40 mg/dL), raised proteins and elevated lactate (> 500 mg%).

Other Investigations

Nonspecific biochemical signs of infection such as moderate leukocytosis, elevated C-reactive protein and erythrocyte sedimentation rate are present. Blood cultures are often sterile unless hematogenous spread of infection has occurred. Definite diagnosis of brain abscess is made only with histopathological examination of brain tissue, demonstration of pus and identification of etiological agent. Specimen obtained from stereotactic aspiration or excision biopsy must be subjected to Gram stain, aerobic, anaerobic, acid-fast bacilli and fungal cultures. As brain abscesses are frequently polymicrobial, newer modalities such as 16S ribosomal DNA polymerase chain reaction amplification may be utilized to increase the number of identifiable bacterial species as opposed to standard cultures.

Search for Source of Infection

A thorough and extensive search for the source of primary infection should be done in all cases. Identification of an infective site may provide a clue to the etiological agent and guide in antimicrobial therapy. Sinus and otogenic infections can be simultaneously identified on MRI brain. Ear and oral cavity inspection is indispensible in all cases of brain abscess as is the screening of heart through echocardiography. Consecutive blood cultures may be required if endocarditis is suspected.

DIFFERENTIAL DIAGNOSIS

Brain abscess needs to be differentiated from other causes of intracranial suppuration and space occupying lesions as well as with more diffuse forms of CNS infection such as viral encephalitis. Herpes encephalitis with frequent focal neurological signs may mimic a brain abscess. Subdural empyema, another form of intracranial suppuration often presents with high-grade fever and prominent meningismus which is usually not seen with brain abscess. Tuberculoma and neurocysticercosis commonly present as first episode of afebrile seizure and generally are not associated with progressive neurological signs. Primary brain tumors have a more indolent course and slow progression over months unless complicated by bleed, secondary infection or obstructive hydrocephalus. It may not be always possible to differentiate these on clinical ground and neuroimaging is required for diagnostic clarification. It is prudent to say that even early CT findings are nonspecific for brain abscess. Early edema with mild-to-moderate mass effect on CT may be seen with tumor, stroke and parasitic infections. Stroke resulting from vasculitis may mimic MRI findings of cerebritis. Newer MRI modalities such as DWI, proton magnetic resonance spectroscopy (MRS) and perfusion scans are required in doubtful cases.

MANAGEMENT

Successful treatment of brain abscess requires prompt and appropriate antimicrobial therapy combined with surgical drainage in most cases. If surgical excision or drainage is planned, it should be performed early in the course of therapy.

Antimicrobial Therapy

Choice of Antibiotics

Treatment with antibiotics is commenced as soon as the diagnosis is established on imaging on an empirical basis. The initial choice is a combination of broad-spectrum antibiotics with good CNS penetration. The empirical antibiotic regime must provide

cover for anaerobes (third-generation cephalosporins and metronidazole) and include vancomycin if methicillin-resistant *Staphylococcus aureus* is suspected or history of penetrating trauma or neurosurgical intervention is present. Further antibiotic therapy would depend upon the culture and antibiotic sensitivity. If cultures fail to show any organisms, these antibiotics should be continued. Suggested choice of antibiotics according to site of infection and probable organism is provided in **Box 1**.

Duration of Antibiotics
The exact duration of antibiotics required for treatment of brain abscess is unclear. Most authors recommend a 4–6 weeks intravenous antibiotic therapy for surgically drained bacterial abscess and a 6–8 weeks therapy when medical therapy is solely offered. Immunocompromised children may require a longer duration with additional cover for atypical organisms. Cerebritis may require a shorter duration compared to a fully encapsulated abscess. Multiloculated abscess or abscesses may require a longer therapy.

Role of Oral Antibiotics
No data is available to recommend or refute oral antibiotic therapy. However, oral drugs often fail to penetrate blood-brain barrier and do not achieve the minimal inhibitory concentration for most of the microorganisms within the abscess. This method of completing antibiotic course must be reserved for those cases where drug sensitivity of the isolated organisms shows good sensitivity to any of the oral medications known to have good CNS penetration.

Surgical Treatment
Neurosurgeon should be involved early in the course of therapy. Indications for Surgical management are provided in **Box 2**. The surgical management may be in form of excision or drainage. Drainage is either performed through burr hole, craniotomy or stereotactically. The choice of surgical procedure has not been found critical in deciding the outcome of the case and should depend upon the surgical expertise available and the hemodynamic status of the child. Deep-seated abscess, small abscess and those involving eloquent cortical regions are preferably drained using stereotactic aspiration and aspiration via craniotomy or craniectomy or excision is performed in superficial abscess or abscess located in the posterior fossa.

Supportive Care
Raised intracranial pressure is often seen and treatment must be directed to symptomatic management of raised ICP. Headache and fever may show complete or partial response to regular

---

BOX 1 Suggested empirical antibiotic therapy for brain abscess
If predisposing factor is of oral, sinus or otogenic origin: Ceftriaxone (100 mg/kg/day in two divided doses)/cefotaxime (200 mg/kg/day in two divided doses)* *plus* metronidazole (15 mg/kg IV loading followed by 7.5 mg/kg IV eight hourly)
If cyanotic congenital heart disease is the predisposing factor: Ampicillin-sulbactam (50–100 mg/kg 6 hourly) alone *or* ceftriazone/cefotaxime (dosage as above) *plus* metronidazole (dosage as above)
In postoperative brain abscess: *Ceftazidime (50 mg/kg/dose 8 hourly) *or* cefepime (50 mg/kg/dose 8–12 hourly *or* meropenem (40 mg/kg/dose 8 hourly) *plus* vancomycin (60 mg/kg/day in 3–4 divided doses)**
*Ceftazidime (50 mg/kg/day q 8 hourly) may be considered if *Pseudomonas* suspected.   **Replace with cloxacillin/oxacillin/nafcillin if culture reveals methicillin-sensitive *Staphylococcus aureus*.

BOX 2 Indications for surgical drainage of brain abscess
• Abscess larger than 2.5 cm   • Aspiration of larger abscesses involving noneloquent cortex in cases of multiple abscesses.   • When abscess size is increasing after 2 weeks of antibiotic therapy   • No decrease in abscess size after 3–4 weeks of antibiotics   • Multiloculated abscess   • Traumatic abscesses with bone chips or foreign material   • Fungal brain abscesses

antipyretics. The role of corticosteroids in treatment of brain abscess is controversial. Studies have shown that steroid inhibit capsule formation, interfere with inflammatory response, decrease antibiotic concentration inside the abscess, increases risk of ventricular rupture and alter CT findings. They are however indicated in children with signs of impending herniation secondary to mass effect caused by massive perilesional edema.

Antiepileptics are required in all children who develop seizures. Phenytoin, carbamazepine, and valproate are equally effective. The duration of antiepileptics depends upon the imaging and electroencephalographic findings. Generally, a 1–3 months course is sufficient, provided no further seizures have occurred.

Monitoring and Follow-up
Magnetic resonance imaging of brain or CT scan can be used for monitoring response to therapy. A repeat CECT should be done urgently in case of sudden neurological deterioration. Else, it is to be repeated after 2–4 weeks of initiation of medical therapy to document the change in size of abscess and resolution.

Management of Brain Abscess in an Immunocompromised Child
Apart from the typical bacterial organisms, *Mycobacterium tuberculosis* and fungal organisms such as *Aspergillus, Nocardia, Candida* and *Mucor* are the common causes of brain abscess. Empirical therapy should be avoided in immunocompromised patients and every effort should be made in establishing a microbiological diagnosis.

PROGNOSIS AND OUTCOME
Brain abscess in children is associated with very high mortality and morbidity. With advent of newer neuroimaging modalities, antibiotic therapy, the mortality has reduced from 30–60% in the preimaging era to 3–25%. Mortality is directly related to the neurological status at admission. Rupture of abscess into the ventricles and posterior fossa location are associated with rapid deterioration and a very high mortality rate. Poor prognostic markers noted by various authors are provided in **Box 3**. Common neurological sequelae are delayed onset seizures (commonly seen with frontal lobe abscess), mental retardation and focal neurological deficits.

BOX 3 Poor prognostic markers of brain abscess
• Neonatal or infantile age group   • Rapidly progressive symptomatology before hospitalization   • Low Glasgow Coma Score at admission   • Rupture into ventricles   • Posterior fossa location   • Multiloculated multiple abscesses   • Immunocompromised state   • Fungal abscess

IN A NUTSHELL

1. Brain abscess is a focal intraparenchymal pus collection with microorganism seeding occurring from contiguous, hematogenous or direct inoculation.
2. Untreated CCHD and sino-otic infections are the most common predisposing risk factors for pediatric brain abscess.
3. Brain abscess associated with hematogenous spread are often multiple in number and generally located in the distribution of middle cerebral artery.
4. The most common microorganisms causing brain abscess in children worldwide are aerobic and anaerobic streptococci.
5. The causative organism usually depends upon immune status of the child and source of primary infection. In 30% cases, brain abscess is polymicrobial.
6. Magnetic resonance imaging of brain with gadolinium is the imaging modality of choice for diagnosing brain abscess.
7. Lumbar puncture is contraindicated in brain abscess with significant mass effect due to risk of sudden herniation and collapse.
8. Successful treatment of brain abscess requires prompt and appropriate antimicrobial therapy combined with surgical drainage in most cases.
9. Broad-spectrum antibiotic cover until culture reports are available should be empirically initiated. Duration of antibiotic treatment should be at least 4–6 weeks in surgically drained abscess and 6–8 weeks in surgically untreated cases.
10. Follow-up CECT should be done urgently in case of sudden neurological deterioration or after 2–4 weeks of initiation of medical therapy.

Chapter 42.20
Inflammatory Demyelinating Disorders
Bindu PS

The inflammatory demyelinating disorders of the central nervous system comprise a spectrum of disorders affecting the white matter of the brain and the spinal cord. Demyelination or loss of myelin of the white matter which is a key feature of these disorders can be either primary or secondary. The secondary demyelinating disorders result from infectious, ischemic, metabolic or hereditary disorder. The etiology of primary demyelinating disorders is unclear but thought to be multifactorial. The primary demyelinating disorders constitute a heterogenous group of disorders and include acute disseminated encephalomyelitis (ADEM), clinically isolated syndrome, pediatric multiple sclerosis (MS) and neuromyelitis optica (NMO). These conditions can be monophasic, relapsing remitting or progressive and can have a highly localized or diffuse involvement of the central nervous system. The prognostic and therapeutic implications necessitate a proper diagnostic classification of these disorders at onset.

The International Pediatric Multiple Sclerosis Study Group has proposed consensus definitions for demyelinating disorders in children to aid in standardization of diagnosis, investigations and further research. This chapter discusses the consensus definitions, different clinical phenotypes, differential diagnoses, diagnostic evaluation and approach to classification, management and outcome of primary inflammatory demyelinating disorders of the central nervous system in children.

DEFINITIONS

The International Pediatric Multiple Sclerosis Association has formulated consensus definitions for diagnosis of acute demyelinating disorders in children **(Table 1)**.

EPIDEMIOLOGY

The demographic characteristics and geographic distribution vary widely among different groups of demyelinating disorders. The incidence of acquired demyelinating diseases in population-based studies range between 0.66 and 1.66 per 100,000 population.

ACUTE DISSEMINATED ENCEPHALOMYELITIS

Epidemiology
Mean age at presentation of pediatric ADEM ranges between five and eight years. Gender ratio is either balanced or shows male preponderance. Data on the incidence of ADEM are sparse. Prevalence is expected to be high in resource poor settings because of the proposed role of antecedent infections in the etiology of acute demyelinating disorders.

Etiopathogenesis
Etiology of ADEM is not clear. A high incidence of seasonal distribution and diverse antecedent viral and bacterial diseases reported in patients with ADEM links to an infectious etiology. The pathogenesis is autoimmune-mediated and is based on *molecular mimicry*. The infectious agents serve as an antigenic trigger which

shares epitopes with various autoantigens of myelin such as myelin basic protein and myelin oligodendrocyte protein. The antigenic trigger activates the T-cells which cross the blood-brain barrier and react against myelin epitopes. Vaccines especially the influenza, rabies and smallpox vaccines have been reported to precipitate ADEM. Pathologically, ADEM is characterized by periventricular infiltrates of lymphocytes, macrophages and occasional plasma cells with edematous and demyelinated adjacent white matter. Multifocal and diffuse lesions are found in gray matter, white matter and spinal cord. All lesions are of the same age and axonal injury is minimal.

Clinical Features
The presentation of ADEM can be wide and range from minimal symptoms to a fulminant course. Children may present with multifocal neurological signs such as hemiparesis, paraparesis, unilateral or bilateral pyramidal signs, cranial nerve deficits, ataxia, visual loss due to optic neuritis, seizures, slow or slurred speech or aphasia and sensory symptoms. Respiratory failure secondary to brainstem involvement or severely impaired consciousness can occur. A rapidly progressive course with resultant mortality is seen in fulminant form of ADEM. Multiphasic ADEM refers to two episodes consistent with ADEM separated by three months but not followed by any further events. Recurrent ADEM is a rarity and has been eliminated from the recent classifications. Relapsing diseases which follows after the second episodes of ADEM indicates a chronic disorder, most often leading to the diagnosis of MS or NMO.

Diagnostic Evaluation
Magnetic resonance imaging shows multiple lesions which are large 1–2 cm diameter **(Figs 1A to F)**. Gadolinium enhancement in one or more lesions can be seen. Different patterns of contrast enhancement can be present and include open ring and nodular enhancement. Periventricular lesions are less common relative to MS, but lesion number location and size are variable. Hypointense lesions on magnetic resonance imaging are rare in ADEM. Lesions in the thalamus and basal ganglia are more typical of ADEM than in MS. Extensive lesions in spinal cord also suggest the diagnosis of ADEM.

Spinal fluid examination is mandatory in a child who presents with acute neurological deficit. Cerebrospinal fluid findings are usually abnormal showing a moderate pleocytosis with elevated protein content. The presence of cerebrospinal fluid pleocytosis does not differentiate ADEM from clinically isolated syndrome or NMO. Cerebrospinal fluid oligoclonal bands may be seen in ADEM but tend to be transient.

Treatment
Treatment of acute inflammatory demyelinating disease requires that other possible diagnoses, especially infectious, neoplastic and metabolic disorders are carefully excluded. The mainstay of acute therapy for all inflammatory demyelinating central nervous system disorders are corticosteroids. Intravenous steroids are required to shorten the acute inflammatory process and hasten recovery. Subsequent oral steroid taper for a duration of 4–6 weeks is recommended for ADEM. Duration of taper less than 3 weeks has been associated with an increased risk of relapse.

Prognosis
Acute disseminated encephalomyelitis is a monophasic illness. The risk factors for MS following a first episode of acute demyelination

Table 1 Definitions of acquired demyelinating disorders

Disorder	Definitions
Acquired demyelinating encephalomyelitis	1. A first polyfocal clinical CNS event with presumed inflammatory cause. 2. Encephalopathy that cannot be explained by fever is present. 3. No new clinical and MRI findings emerge three months or more after the onset 4. Brain MRI abnormal during the acute phase 5. *Typically on MRI:* Diffuse poorly demarcated large (> 1–2 cm) lesions involving predominantly the cerebral white matter; T1 hypointense lesions are rare; deep gray matter lesions (e.g., thalamus and basal ganglia) can be present
Recurrent ADEM	This was defined previously as a new event of ADEM with a recurrence of the initial symptoms and signs, 3 or more months after the first ADEM event, without involvement of new clinical areas by history, examination, or neuroimaging. *Now this has been subsumed under multiphasic ADEM.*
Multiphasic demyelinating encephalomyelitis	ADEM followed by a new clinical event also meeting criteria for ADEM, but involving new anatomic areas of the CNS as confirmed by history, neurologic examination, and neuroimaging. The event must develop within 3 months of the initial event.
Pediatric multiple sclerosis	1. Two or more nonencephalopathic CNS clinical event separated by more than 30 days, involving more than one area of CNS. 2. Single clinical event and MRI features consistent with 2010 revised McDonald criteria* for dissemination in space and time. 3. ADEM followed three months later by a nonencephalopathic clinical event with new lesions on MRI consistent with MS

Neuromyelitis optica (NMO)	1. Optic neuritis
	2. Acute myelitis as major criteria and
	3. At least two of the three supportive criteria
	    a. Contiguous spinal cord MRI lesion extending over three or more segments
	    b. Antiaquaporin-4-IgG seropositive status
	    c. Brain MRI not meeting the diagnostic criteria for MS

Clinically isolated syndrome (CIS)	1. A first acute clinical episode of CNS symptoms (without encephalopathy) with a presumed inflammatory demyelinating cause 2. Absence of prior clinical history of CNS demyelinating disease. 3. No encephalopathy (no alteration in consciousness or behavior that cannot be explained by fever) 4. The diagnosis of MS based on baseline magnetic resonance features is not met.

Adapted from Krupp et al. 2007 and 2013

Abbreviations: ADEM, acute disseminated encephalomyelitis; CNS, central nervous system; MRI, magnetic resonance imaging; MS, multiple sclerosis.

*The 2010 Revised McDonald criteria for dissemination in space require one or more T2 lesion in at least two out of the four locations: periventricular, juxtacortical, infratentorial, and spinal cord. The 2010 Revised McDonald criteria for dissemination in time can be satisfied by the emergence of new T2 lesions (with or without enhancement) on serial scans or can be met on a single baseline scan if there exists simultaneous presence of a clinically silent gadolinium-enhancing lesion and a nonenhancing lesion.

include age greater than 10 years, absence of encephalopathy, absence of precipitating infection, presence of optic neuritis, presence of intrathecal oligoclonal bands, family history of MS and periventricular perpendicular ovoid lesions (PPOL). Factors associated with a decreased relapse include age less than 10 years of age, encephalopathy, postinfectious presentation, isolated transverse myelitis, meningism or seizures. Comparison of clinical and magnetic imaging features between acute disseminated encephalomyelitis and multiple sclerosis is given in **Table 2**.

PEDIATRIC MULTIPLE SCLEROSIS

Epidemiology

About 3–10% of the MS patients manifest during childhood. Gender ratio varies with age. A female preponderance is reported in patients with onset of MS in adolescence. However, there is no gender predilection in children presenting with MS before 6 years of age.

Etiopathogenesis

Environmental factors have been implicated in the susceptibility of children to multiple sclerosis. Three important factors are: (1) vitamin D deficiency; (2) viral infections, particularly Epstein-Barr virus, herpes virus and varicella zoster; (3) exposure to cigarette smoke. Parental smoking has been identified as a risk factor with an

increased level of risk after longer duration of exposure. Currently, there is no evidence on possible triggering events of vaccination on the manifestation of pediatric MS. Studies have shown that in children vaccinated after the first episode of demyelination neither tetanus nor hepatitis B vaccination increased the risk of conversion.

Clinical Features

Diagnosis of multiple sclerosis is defined by recurrent attacks of inflammatory demyelination. Presenting features include motor deficits, sensory dysfunction, brainstem symptoms, optic neuritis and ataxia. Isolated transverse myelitis is an uncommon presentation of MS in children. Optic neuritis in MS tends to be unilateral compared to NMO. The diagnosis of pediatric MS requires multiple episodes of central nervous system demyelination separated in time and disseminated in space. In patients less than 10 years of age, the dissemination in time and space should be preferably a clinical one and secondly the diagnosis of ADEM should be excluded. The prognosis in the patients less than ten years of age is generally good. Most patients in the adolescent age group experience the second attack of demyelination within 1 year, whereas children below 10 years have a longer attack interval. Even though the course is most often relapsing remitting in the beginning, patients develop permanent physical disability, spasticity, tremor, or bladder dysfunction over time.
Figures 1A to F Brain magnetic resonance imaging in a 7-year-old boy with acute disseminated encephalomyelitis. White matter lesions are present in A (axial view) and E (sagittal view): Lobar white matter; (B) Thalamus; (C) Internal capsule; (D) Corpus callosum; (F) Middle cerebellar peduncle

Table 2 Comparison of clinical and magnetic resonance imaging features between acute disseminated encephalomyelitis (ADEM) and multiple sclerosis

Characteristics	ADEM	Multiple sclerosis
Age of onset	Younger	Older
Gender preference	Nil	Female preponderance
Antecedent event	Common	Uncommon
Prodormal symptoms	Common	Uncommon
Onset	Acute	Subacute
Headache, vomiting, fever	More common	Less common
Altered sensorium	More common	Unlikely
Seizures	More common	Less common
Meningism	More common	Less common
Pattern of CNS involvement	Usually multifocal	Usually single site
Optic neuritis	Bilateral	Unilateral
Transverse myelitis	Complete	Incomplete
CSF protein	Elevated	Normal/mild elevation
CSF pleocytosis	Variable	< 50/cmm
CSF oligoclonal bands/intrathecal IgG production	Transient	Persistent
MRI lesion load	Extensive (Symmetric/asymmetric)	Scattered asymmetric
MRI—white matter distribution	Usually subcortical	Usually periventricular
MRI—corpus callosum involvement	Less common	Common
MRI—predominant brainstem involvement	More common	Less common
MRI—thalamus, basal ganglia involvement	More common	Less common
MRI—lesion margin	Ill-defined	Defined
MRI—enhancement of lesions with contrast	Usually uniform	Nonuniform
Serial MRI	Resolution of lesions; no fresh lesions, new lesions occur only in association with symptoms	Asymptomatic lesions can be seen

The Kurtze *expanded disability status scale* (EDSS) is a method of quantifying disability in multiple sclerosis. The scale quantifies disability in five functional systems namely pyramidal, cerebellar, brainstem, sensory, bowel and bladder, visual, cerebral and others. This allows the physician to assign a score in each of these systems. Retrospective longitudinal studies of pediatric onset MS patients indicate that majority of the patients will progress to secondary progressive MS. Primary progressive MS in which patients experience progressive disability from onset without clinical relapses is exceptionally rare in children. There are no serologic or immunologic factors known to predict MS risk at the time of first inciting event. There are no biologic markers that can distinguish multiple sclerosis from other demyelinating disorders.

Diagnostic Evaluation

Magnetic resonance imaging features of childhood MS are characterized by multiple white matter lesions. Pediatric patients tend to have less number but bigger lesions described as tumefactive lesions **(Fig. 2)**. This is due to the brief subclinical phase, immaturity of myelin system, and immunologic immaturity. In addition children may differ in their innate capacity for myelin repair leading to fundamental differences in the appearance of white matter lesions. This is particularly true for children with onset of MS before 10 years of age. Diffuse bilateral white matter lesions with ill-defined borders are common. Despite the dramatic appearance of the lesions, resolution of the initial lesions may be seen. The magnetic resonance imaging features of pediatric MS patients with onset above ten years often resemble that of adults with MS and is characterized by multiple, well-demarcated, homogenous small ovoid lesions often described as PPOL **(Fig. 3)**. The spinal cord lesions in MS tends to be located peripherally and typically involve short segments less than one vertebral body in length. The presence of hypointense lesions or *black holes* on T1-weighted MRI scans may indicate a chronic demyelinating process.

Different sets of magnetic resonance imaging criteria have been tested for their utility for diagnosis of multiple sclerosis in children and include 2010 Revised McDonald criteria, kids with multiple sclerosis (KIDMUS) criteria, and criteria proposed by Callen et al. and Verhey et al. The 2010 Revised McDonald criteria is currently being used to facilitate early diagnosis of MS in children based on adult studies. However, this has a less predictive value in the context of younger children and is not appropriate when there is an ADEM like presentation.

Intrathecal oligoclonal bands in the cerebrospinal fluid detected by isoelectric focusing are a feature of multiple sclerosis. Cerebrospinal fluid oligoclonal bands are reported in 72–84% of children with MS. Neurophysiological testing such as visual and auditory evoked potentials is also of diagnostic importance in detecting subclinical evidence of demyelination.

Treatment

All acute relapses of multiple sclerosis should be treated by intravenous corticosteroids. In contrast to ADEM, steroid taper in pediatric multiple sclerosis should be restricted to those patients with insufficient resolution of symptoms or those patients who experience symptoms after discontinuation of intravenous steroids and should be kept as short as possible. A second pulse of methyl prednisolone may be necessary in children with severe symptoms not responding sufficiently to the first course of corticosteroids. In case of fulminant demyelination plasma exchange should be considered timely.

Long-term disease modifying therapy Initiation of immuno-modulatory therapy is suggested in pediatric multiple sclerosis patients with active relapsing remitting disease as suggested by more than one clinical exacerbation/new/enhancing lesions on repeat MRI over a period of 2 years. The first-line drugs include interferon B and glatiramer acetate. Azathioprine is a secondary treatment option. The available literature on the use of interferon and glatiramer acetate in pediatric patients is restricted to tolerability data in isolated small case series or case reports.

NEUROMYELITIS OPTICA

Reports of NMO in children are sparse. Prospective studies report a relatively low frequency of pediatric NMO. A female preponderance is reported in NMO-IgG positive patients. Female-to-male ratio is near equal for the monophasic form.

Etiopathogenesis

Pathology of NMO is characterized by perivascular inflammation, often with infiltration of eosinophils and neutrophils as well as immunoglobulin and complement deposition. The serum autoantibody, aquaporin-4 (AQP4) antibody has been identified as a specific marker in patients with NMO. This antibody reacts with
Figure 2 Tumefactive demyelination in a 7-year-old boy. Note the large white matter lesions resembling a tumor with open ring enhancement
Figure 3 Brain magnetic resonance imaging shows discrete white matter lesions (periventricular perpendicular ovoid lesions) in a 14-year-old girl with relapsing remitting multiple sclerosis

the water channel protein AQP4 which is densely expressed in the astrocyte foot processes of astrocytes at the blood-brain barrier.

Clinical Features

Neuromyelitis optica is an inflammatory disease of the central nervous system that preferentially affects the optic nerves and spinal cord. Traditionally, the term NMO was applied to patients who experienced a monophasic event consisting of simultaneous optic neuritis and acute myelitis. Neuromyelitis optica spectrum is now recognized to typically evolve as a relapsing disorder and include patients with unilateral optic neuritis and myelitis occurring weeks or even years apart. A variety of extraneurological manifestations such as intractable vomiting, anorexia and weight loss have also been described as the presenting manifestation of these patients. These symptoms are attributed to the highly specific involvement of certain brain regions such as hypothalamus and medullary centers in these patients.

Magnetic resonance imaging may show signal intensity changes in the optic nerve with gadolinium enhancement. The spinal cord lesions are longitudinally extensive and involve more than three vertebral segments **(Fig. 4)**. The brain lesions in NMO are preferentially located at the sites of high aquaporin 4 expression such as hypothalamus and periventricular white matter. When occur, they are not oval or ovoid or perpendicularly located as in lesions of multiple sclerosis, but tend to be punctate small round dots. Few lesions can also be patchy and confluent. A cloud-like enhancement defined as multiple patchy enhancements with blurred margins in adjacent regions in contrast to the isolated spotty enhancement seen in multiple sclerosis may also help differentiating neuromyelitis optica from multiple sclerosis on imaging.

Cerebrospinal fluid examination includes a marked elevation in white cell count (often polymorphonuclear) in addition to elevated protein. In contrast to multiple sclerosis, only a small percentage of the patients show presence of oligoclonal bands.

Treatment

The first-line treatment for NMO is parenteral corticosteroids followed by oral steroids. Plasmapheresis should be initiated if a severe attack does not respond promptly to corticosteroids. This is especially important in cases of ascending cervical myelitis because

Figure 4 Spinal cord MRI (sagittal view) showing longitudinally extensive spinal cord lesions in a child with neuromyelitis optica

of the risk of neurogenic respiratory failure. Distinguishing NMO from multiple sclerosis in early stages is important. Seropositive patients with NMO may require long-term immunosuppressive therapy. Recent case reports and case series have shown that patients with NMO experience clinical deterioration under interferon-B treatment. It is shown that IFN-β treatment is not only ineffective for preventing relapses but also may increase the relapses significantly.

Prognosis of patients with NMO depends on presence of antiaquaporin antibodies. Seronegative patients with NMO usually have a monophasic course. Seropositive patients tend to have relapsing remitting course and the long-term prognosis is poor.

CLINICALLY ISOLATED SYNDROME

Clinically isolated syndrome refers to a first acute clinical episode of central nervous system symptoms with a presumed inflammatory demyelinating cause, for which there is no prior history of demyelinating event. The event is referred as monofocal if the clinical features are referable to a single central nervous

system site such as optic neuritis, transverse myelitis, brainstem, cerebellar or hemispheric lesions. Optic neuritis is defined by acute or subacute visual loss, restricted visual fields and pain with ocular movement. Transverse myelitis results in motor sensory or autonomic symptoms. A brief description of the clinical features and diagnostic evaluation in patients with acute transverse myelitis is given below. If the clinical features are characterized by signs and symptoms attributable to more than one central nervous system sites, the event is referred as polyfocal. The event should not include encephalopathy, though in brainstem syndromes encephalopathy may be present. The classification is purely based on clinical features rather than magnetic resonance imaging findings.

ACUTE TRANSVERSE MYELITIS

It is an acute inflammatory process affecting the spinal cord with relatively abrupt onset of motor, sensory and autonomic symptomatology. Even though most patients have a presumed postinfectious etiology, it can represent the sentinel event of a relapsing demyelinating disorder such as pediatric multiple sclerosis or NMO. It can also occur as an idiopathic monophasic illness. It is typically preceded by a mild illness in the 3 weeks prior to symptom onset, as reported in 50–100% of patients. The criteria for diagnosing transverse myelitis include sensory, motor, or bladder or bowel dysfunction attributable to the spinal cord, with progression to nadir in less than 21 days from onset. The clinical features depend on the location of the lesion. A high cervical cord lesion can present with acute respiratory failure. A sensory level may not be easily elicitable in the pediatric population. Initial evaluation should include a gadolinium-enhanced magnetic resonance imaging of the spine to exclude a compressive myelopathy. Magnetic resonance imaging usually shows hyperintense signal changes on T2W sequences. The extent of the lesions varies. Lesions of acute transverse myelitis in children are typically longitudinal, may demonstrate enhancement and are centrally located. If there is no evidence of a compressive lesion, a lumbar puncture should be performed. Cerebrospinal fluid typically shows pleocytosis and an elevated CSF IgG index. Other investigations recommended include parainfectious markers like virological serology. If there are features to suggest a systemic inflammatory disorder, autoimmune screening and serum angiotensin-converting enzyme levels are indicated. High-dose corticosteroids have shown to have beneficial effect and hasten recovery.

Differential Diagnosis

The differential diagnoses for a child who presents with an acute neurological deficit and white matter lesions on neuroimaging is wide. The features which should alert the clinician include the presence of fever, encephalopathy, involvement of the peripheral nervous system or other organ systems, absence of, or only minimal resolution of attack symptoms, a progressive disease course, elevated erythrocyte sedimentation rate (ESR) or leukocyte count, marked cerebrospinal fluid pleocytosis, and absence of isolated cerebrospinal fluid oligoclonal immunoglobulin G. Contrast enhancement may suggest an infectious, inflammatory or granulomatous disorder. Most often neuroimaging is the first available investigation and a critical look at the magnetic resonance image helps in formulating the differential diagnosis. The features to be looked are size and nature of the lesions (multifocal discrete, confluent or diffuse), topographical distribution of the lesion (predominantly white matter, basal ganglia, thalamus, brainstem, cerebellum) pattern of contrast enhancement (complete ring/ open ring/patchy/diffuse enhancement).

In tropical countries, infections of the central nervous system should be an important diagnostic consideration due to the therapeutic implications. Central nervous system infections that can present with white matter lesions include neurobrucellosis, neuroborreliosis, HIV encephalopathy and subacute sclerosing pan encephalitis. When there is complete ring enhancement of the lesions the differential diagnoses include brain abscess, tuberculoma and toxoplasmosis. When there is contrast enhancement, primary or secondary lymphoma also should be considered. Mutifocal discrete white matter lesions also may suggest primary or secondary central nervous system vasculitic disorders and noninfectious granulomatous disorders like neurosarcoidosis. Inherited disorders to be considered are leukodystrophies and mitochondrial disorders, especially when there is a progressive course.

Diagnostic Evaluation

In the absence of specific biological markers, diagnosis of acute demyelinating disorders is based on a combination of clinical, laboratory and magnetic resonance imaging features. All patients should be evaluated with neuroimaging preferably magnetic resonance imaging and cerebrospinal fluid testing. In the emergency setting a computerized tomogram (CT) of the brain may be necessary to rule out contraindication for a cerebrospinal fluid examination and to rule out other pathologies, especially if there is a delay in obtaining the magnetic resonance imaging. Magnetic resonance imaging of the brain and spinal cord with and without gadolinium should be obtained in all children with an initial demyelinating event. The work-up should also include cerebrospinal fluid studies including cell count with differential, total protein, IgG index, evidence of oligoclonal bands. The preferred method for detection of oligoclonal bands is the qualitative assessment of paired CSF and serum samples with isoelectric focusing. In addition to the routine testing, cerebrospinal fluid should be sent for infectious screening and virological studies, especially when the clinical features suggest an underlying infectious process. Other minimum tests include complete blood count with differential, ESR and antinuclear antibody testing. Expanded blood investigations depend on specific clinical situations. Neurophysiological testing such as visual evoked potentials, somatosensory evoked potentials and brainstem auditory evoked potentials is of additional diagnostic value. Evoked potential studies aid in localization of lesions and confirm organic basis for clinically ambiguous symptoms. Furthermore, evoked potential studies can identify clinically silent lesions, thereby providing objective support for dissemination in space in children with suspected multiple sclerosis.

A broad approach to diagnosis and classification in children with demyelinating disorders are shown in **Flow chart 1**.

IN A NUTSHELL

1. Central nervous system inflammatory demyelinating disorders comprise a group of disorders with heterogenous clinical manifestations.
2. It is important to distinguish monophasic demyelinating syndromes, such as ADEM from relapsing remitting disorders such as multiple sclerosis.
3. Diagnostic evaluation requires a careful exclusion of other similar disorders.
4. Early and correct diagnostic categorization in these children has prognostic and therapeutic implications.

Flow chart 1 Approach to diagnosis of acute demyelinating disorders

Chapter 42.21

Autoimmune and Paraneoplastic Encephalitis and Encephalopathies

Lokesh Lingappa, Sirisharani Siddaiahgari

Encephalopathy in children and adolescents poses difficult diagnostic and therapeutic challenges. A study by the California Encephalitis Project, on the epidemiology and etiology of encephalitis, found that 63% of the patients remained without an etiology after a battery of tests for 16 potential infectious agents. The situation is much more difficult in the developing world in view of limited viral testing facilities. Most common cause in tropical or developing countries is still infection including viral, bacterial, rickettsial, tubercular or malaria. The differential diagnosis must include various noninfectious etiologies including drug-induced encephalopathy, vasculitis, metabolic encephalopathy and autoimmune encephalopathy. Though rare, malignancies can also present with encephalopathy as a presenting feature.

Antibody-mediated encephalopathy is a term used in children presenting with neurological syndrome associated with serum and/or cerebrospinal fluid (CSF) antibodies directed against ion channels, receptors and associated proteins. The clinical features of these disorders overlap and in many cases, the etiology may not be apparent at presentation. Investigation and treatment needs to be ongoing in this clinical situation.

The presenting manifestations vary and include, fever, seizures, amnesia, confusion, psychiatric features and encephalopathy with movement disorder in some. The encephalopathy can be part of a paraneoplastic syndrome. The presence of a tumor depends on the type of autoimmune disorder and gender. Nevertheless, the majority of children do not have any detectable tumor.

Autoimmune encephalitis **(Box 1)** are increasingly being diagnosed in children with antibodies against N-methyl-D-aspartate receptor (NMDAR), voltage-gated potassium channel (VGKC)-complex proteins or other CNS antigens such as glutamic acid decarboxylase. The clinical phenotypes associated with

BOX 1 Types of autoimmune encephalitis

1. N-methyl-D-aspartate receptor (anti-NMDA receptor antibody-mediated) encephalitis
2. Voltage-gated potassium channel related encephalitis
3. Hashimoto encephalopathy
4. Opsoclonus myoclonus syndrome

---

these conditions are increasingly recognized **(Table 1)**. But some patients test negative for antibody tests available as of today.

N-METHYL-D-ASPARTATE (NMDA) RECEPTOR ENCEPHALITIS

N-methyl-D-aspartate receptor encephalitis is the most common autoimmune encephalitis in children worldwide. First described by Joseph Dalmau et al. in 2007, it is now being frequently diagnosed. Children constitute a large part of NMDA receptor encephalitis patients and tumors are present in less than 10% of patients in this age group, compared with 40–50% in women older than 18 years. In a study from UK, 23% of patients with NMDAR encephalitis were under the age of 18 years. Similarly, in a large US cohort, 40% of NMDAR antibody encephalitis presented in childhood or adolescence. Twenty-one percent of patients without a detected infection were found to have a specific antibody-mediated neurological syndrome in one retrospective study. In adults, the disease is commonly paraneoplastic, most frequently associated with ovarian teratoma. In children, associated tumors are rare.

Clinical Features

N-methyl-D-aspartate receptor encephalitis presents as a multistage encephalopathy including psychiatric manifestations, dyskinesias and occasionally limbic encephalitis (LE). Diagnostic criteria are summarized in **Box 2**. The phases of NMDAR encephalitis evolution are better delineated in adults than children. Fever is noted in the prodromal phase in many (phase 1). The various neurological manifestations include psychosis, confusion, amnesia, and dysphasia (phase 2). Some children are seen initially by psychiatrists. Symptoms progress to movement disorders, autonomic instability, hypoventilation, and often reduced consciousness (phase 3).

Choreoathetoid involuntary movements are characteristic, but some patients become mute and catatonic. The syndrome is characterized by severe motor disorder, perioral dyskinesias, and autonomic disturbances along with seizures. Fever is not a necessary presenting feature in these children. The perioral dyskinesias are the diagnostic abnormality which directs toward the diagnoses. This movement disorder is the key clinical feature in children that is characteristically early in onset, progressive in nature, unless intervened by immunomodulation in most.

Autonomic disturbances include brady- and tachyarrhythmias, rarely requiring cardiac pacing in children. Urinary disturbances like incontinence or retention are noted in few patients.

Recovery is often slow, even with immunotherapy and during recovery the clinical features tend to remit in the reverse sequence of their appearance. The symptoms will evolve in sequence, in some patients whereas in some, with less well-defined syndromes, symptoms can overlap, especially in those patients

---

Table 1 Key features of important autoimmune neurological syndromes

Syndrome/ antibodies	Particular clinical features	Possible tumors	Immunotherapy response
NMDA receptor encephalitis/ NMDA receptor antibodies	Most common autoimmune encephalitis Seizures, psychosis, perioral dyskinesias, catatonia, autonomic disturbances, progressive course beyond 2 weeks after onset	Ovarian teratoma rare in preadolescent beyond 18 years—50%	Steroids, IVIG, plasmapheresis—rituximab, cyclophosphamide
Opsoclonus-myoclonus syndrome/ No defining Antibodies	Irritability, chaotic eye movements, myoclonus, ataxia and poor sleep	Neuroblastoma	ACTH, IVIG, rituximab
VGKC antibody related syndromes	Rare in children Psychosis, recent memory impairment, tonic seizures (faciobrachial seizures)	Non-neoplastic Occult neuroblastoma	Steroids, IVIG, plasmapheresis

BOX 2 Key features for diagnoses of NMDAR encephalitis

1. Psychiatric features
2. Memory disturbance
3. Speech disorder
4. Seizures
5. Dyskinesias
6. Decreased level of consciousness
7. Autonomic instability
8. Hypoventilation

N-methyl-D-aspartate receptor antibody encephalitis will have at least 3/8 of the above symptoms within 1 month of onset of disease.

Caution should be exercised in diagnosing anti-NMDA receptor encephalitis when patients after several weeks of disease onset develop only 1 or 2 of the above symptoms.

Figure 2 Postcontrast axial images demonstrating intense gyral enhancement in right occipitotemporal cortex

with psychogenic movement disorders, opsoclonus-myoclonus, or psychiatric syndromes.

Investigations

Magnetic resonance imaging of the brain often does not provide diagnostic information in this condition. The findings described include cortical (usually in the limbic mediotemporal cortex) or subcortical lesions in the brainstem or in the basal ganglia, or the cerebellum. T2 and fluid-attenuated inversion recovery (FLAIR) hyperintensities or contrast enhancement in cortical meninges or basal ganglia are detected **(Figs 1 and 2)**. MRI brain images are normal in more than 50% of cases.

The EEG may be abnormal at onset. Widespread interictal and ictal epileptiform activity arising from the cortex can be seen in some patients during the early stage of the disease. At later stages, generalized diffuse dysrhythmic high-amplitude slowing is seen. Extreme *delta brush* pattern is termed because of its resemblance to the delta brush (beta-delta complexes) pattern seen in premature infants, is seen in some children with anti-NMDAR encephalitis. CSF reveals moderate lymphocytic pleocytosis (median 32 cells per μL, range 5–480 cells per μL) at onset. Many may have completely normal CSF. Oligoclonal bands are detected in the CSF in later stage of illness. Viral polymerase chain reactions need to be performed in these children as they are most common differential diagnoses in this condition.

NMDAR antibodies These are detected both in serum and CSF with sensitivity in the CSF being marginally better than serum. Titers in

serum are higher than those in the CSF but when normalized to total IgG concentrations (which are about 300–400 times higher in the serum), almost all patients show high intrathecal synthesis of NMDAR antibodies. The persistence of antibodies for long period of time is noted in this condition and needs to be interpreted in conjunction with the clinical situation. Increasing titers on follow-up with clinical worsening is an indication for retreatment.

Differential Diagnosis

A high index of suspicion and awareness of the clinical phenotype is essential for appropriate diagnosis. The disorders with similar presentation which must be considered in the differential diagnosis include viral encephalitis, acute disseminated encephalomyelitis, central nervous system vasculitis and acute decompensation in inborn errors of metabolism.

Treatment

Studies have demonstrated clear clinical benefit in altering the course of the illness, if the treatment is started early. Patients with paraneoplastic etiology seem to have better outcomes than those with nonparaneoplastic disease particularly if they undergo tumor removal (and usually immunotherapy) within 4 months of presentation. Treatment regimes start with intravenous steroids followed by intravenous immunoglobulins. Many respond to these treatment options. Rituximab and cyclophosphamide are second-line medications, if children progress despite these medications. In many series, children respond to rituximab more often than first-line drugs. Cyclophosphamide subsequently, if required, seems to improve outcomes in resistant cases.

Outcome

The outcome of these patients is often good, but recovery can be slow and 15–25% of patients relapse. The recovery can take up to 2 years in these children and many come back to the baseline level of activities, especially those who are treated early in the course of illness.

Children without a tumor have increased risk of recurrence as compared to those with tumor. Presenting symptoms during relapse are similar to the initial presentation. Inadequate treatment of the first episodes, or occult tumors, might have been partly responsible for some relapses. Some fully recovered patients can still have detectable levels of antibodies in serum or CSF, suggesting a potential for reactivation of the immune response and clinical relapses in children with anti-NMDA receptor encephalitis.

Figure 1 Axial FLAIR MRI demonstrating hyperintensities in right occipitotemporal cortex

HASHIMOTO ENCEPHALOPATHY

Hashimoto encephalopathy is an ill-defined entity as the syndrome and immunological findings are unclear. There are less than 50 pediatric cases reported in the English literature. Hypothyroidism is seen in around 50% of affected children and rest are euthyroid; rarely few develop hyperthyroidism.

The clinical features include sleep and behavior abnormalities, stroke-like symptoms, tremor, myoclonus, transient aphasia, seizures, and ataxia. The MRI of the brain is usually normal. Cerebrospinal fluid protein level may be elevated. EEG studies show features of background slowing consistent with degree of encephalopathy. The thyroid function tests may be normal. The diagnostic investigation of this condition is detection of thyroid peroxidase antibodies (anti-TPO antibodies) along with a constellation of the clinical symptoms and response to corticosteroids.

The treatment of choice is steroids, about 50% of children respond to steroids. As in other autoimmune disorders plasma exchange or intravenous immunoglobulin have been effective in few cases.

VOLTAGE-GATED POTASSIUM CHANNEL ANTIBODY-MEDIATED ENCEPHALITIS

Voltage-gated potassium channel antibody-associated LE was the first immunotherapy responsive neuronal surface antibody-associated CNS syndrome to be well characterized. It is extremely rare in pediatric age group (case series and reports) and has typical presentation with memory problems and seizures.

Antibodies to VGKC, GAD65, Hu, Ma2 have been reported in this clinical setting along with neuronal secreted protein called leucine-rich glioma-inactivated 1 (LGI1). These antibodies were previously thought to target the voltage-gated potassium channel. The current understanding is that LGI1 is a secreted neuronal protein that interacts with the presynaptic and postsynaptic proteins ADAM23 and ADAM22 that act to modulate synaptic transmission. The presenting features of patients with LGI1 include severe short-term memory loss, hyponatremia, and seizures, described as faciobrachial dystonic seizures or tonic seizures.

MRI evidence of medial temporal lobe inflammation is noted in approximately 60% of patients but pleocytosis or other CSF changes are uncommon, and oligoclonal bands are rare.

Treatment with intense immunotherapies has yielded good outcomes in about 70% of patients. Spontaneous improvements have been documented in some patients. A rarer condition associated with VGKC-complex is Morvan's syndrome, characterized by insomnia and psychosis, peripheral nerve hyperexcitability (including neuromyotonia and pain) and dysautonomic features. CASPR2-Abs are more common than LGI1-Abs in Morvan's syndrome. This condition is rarely seen in children.

RASMUSSEN ENCEPHALITIS

Rasmussen encephalitis is a constellation of features comprising a triad of refractory partial seizures, focal weakness (usually hemiparesis) and hemispheric atrophy. The etiology includes focal cortical dysplasias, gliosis secondary to perinatal injury and vascular malformation. When the initial neuroimaging does not reveal structural malformations, a possibility of autoimmune etiology is considered. This is an inflammatory encephalopathy characterized by progressive refractory partial seizures, cognitive deterioration, and focal deficits that occur with gradual atrophy of one brain hemisphere.

Children frequently present between 6 years and 8 years. Multiple theories have been proposed as there is no single etiological factor.

There is no clear explanation for unilateral involvement of brain in Rasmussen encephalitis. There is no diagnostic antibody testing for this condition. CSF is usually normal, and initial MRI is normal and later progress over period of weeks to months to develop progressive hemispheric atrophy.

High-dose methylprednisolone and intravenous immunoglobulin may be effective in early stages of disease. Rituximab and intraventricular alpha-interferon have been effective in a few isolated cases. The only definitive treatment is functional hemispherectomy that consists of surgical disconnection of the affected hemisphere.

OPSOCLONUS MYOCLONUS SYNDROME

Opsoclonus myoclonus syndrome (OMS) is a clinical constellation of evolving ataxia, opsoclonus with regression of speech or encephalopathy in presence of normal neuroimaging. Two to four percent of children with neuroblastoma develop OMS, which has a higher frequency of paraneoplastic syndrome than in most other cancers. OMS has a predilection for toddlers, and most cases are diagnosed before the age of 5 years as is the case with neuroblastoma.

The complete clinical syndrome may take time to evolve. Many of these, children present with isolated ataxia persisting beyond the first two weeks as seen classically in the postinfectious cerebellar ataxia. Opsoclonus is distinguished from nystagmus by its multidirectional, erratic, darting quality. The opsoclonus with irritability is a presenting manifestation in a proportion of children. Hence, a careful assessment of the abnormal eye movement along with pediatric ophthalmologist and verifying history of myoclonus or speech disturbances are helpful in making diagnoses. Myoclonus is subcortical in nature. It consists of muscle jerks of both small and larger amplitudes giving a tremulous appearance. They are action induced, but in severe cases, can be present at rest. Ataxia in OMS begins as gait ataxia, with falling and poor coordination, and progresses to include titubation and loss of ambulation. In rare situations, the tremors are so severe that all other manifestations may be masked precluding the accurate diagnoses.

Children with OMS are highly irritable and aggressive secondary to significant sleep disturbance. Cognitive impairment is noted in children with most severe course and multiple relapses. In these children, the IQ declines over a decade but then stabilizes later on. Other long-term behavioral issues include attention-deficit disorder and persistent rage but those are potentially treatable.

Investigation

Children presenting with ataxia need to have MRI brain performed to exclude other diagnosis. MRI of the brain is normal in OMS. All children with opsoclonus myoclonus syndrome need to be evaluated for presence of underlying neuroblastoma (Fig. 3). Routine CSF evaluation is normal in these children. Yield rate of spot urine vanillylmandelic acid (VMA) or 24-hour urine VMA analysis is poor.

High-resolution CT of chest, abdomen, and pelvis, carried out with oral contrast, probably has the highest yield. The size of tumor can be small in some children. If the CT is normal, a ^{131}I-metaiodobenzylguanidine (MIBG) scan is sensitive for neuroblastoma. If initial investigations are normal, these children should be screened every 6 months for up to 1 year from diagnoses of OMS.

Treatment

The current proposed treatment options include steroids (ACTH, dexamethasone), and/or IVIG. If the child is still encephalopathic
Figure 3 T2WI axial images—bilateral medial temporal signal changes noted in a child with neuroblastoma and limbic encephalitis

therapy to achieve complete remission along with prevention of relapses might help to reduce this long-term morbidity.

<div style="border:1px solid; padding:8px;">

IN A NUTSHELL

1. N-methyl-D-aspartate receptor antibody-mediated encephalitis is the most common autoimmune encephalitis in children.
2. N-methyl-D-aspartate receptor encephalitis is commonly paraneoplastic in adults, with ovarian teratoma being the most commonly associated tumor. In children, associated tumors are rare.
3. The characteristic clinical features of NMDAR encephalitis include seizures, psychosis, perioral dyskinesias, catatonia, autonomic disturbances, and progressive course beyond 2 weeks after onset.
4. The diagnosis is confirmed by the presence of NMDAR antibodies in the serum and CSF.
5. Treatment options include steroids, IVIG, plasmapheresis and in refractory cases rituximab.
6. Early treatment leads to a better clinical outcome.

</div>

or nonambulant even 3 months into treatment, rituximab needs to be started early to improve the long-term outcome. Surgery is done in children with a tumor, and chemotherapy depending on the stage and complete or incomplete removal.

Prognosis

Factors predicting poor prognosis include infantile onset, loss of ability to walk or speak at onset, incomplete response to treatment, and multiple relapses. The course of OMS is not affected by presence or absence of a tumor. Relapses are noted in more than 50% of children. Majority are left with residual behavioral, language, and cognitive problems. An early and aggressive immunomodulatory

Chapter 42.22
Headache
Devendra Mishra

Headache is an extremely frequent occurrence in childhood and adolescence and is among one of the commonest reasons for a neurological consultation. The prevalence of primary headache ranges from 10% to 20% in school-aged children and increases with increasing age. Headache in a child may either represent a primary headache disorder such as migraine or tension-type headache (TTH), or may be a secondary headache due to an underlying neurological or non-neurological condition. Although validated diagnostic criteria for the diagnosis of headache disorders exist, the primacy for the pediatrician is to rule out serious underlying neurological disorder. History and clinical examination are the keys to headache management, with investigations infrequently required.

EPIDEMIOLOGY

Some geographical differences in the prevalence of headache and migraine are known, but the overall trend in occurrence is similar worldwide. Migraine is the third-most prevalent disorder and seventh-highest specific cause of disability worldwide. In a population based neuroepidemiological survey of more than one hundred-thousand individuals (34% < 15 years) in India in 2004, headache was the most frequent disorder diagnosed with prevalence rate of 1,119 per 100,000. Hospital-based studies among adults in India have reported migraine and TTH to be the most common headache disorders.

In an epidemiological survey of headache among 9,000 schoolchildren, one-third of the 7-year-old and half of 15-year-old children reported having at least one headache episode, thereby documenting for the first time, the high prevalence of headache in children. By age 15 years, around 5% of these children had experienced migraine. Migraine is reported to be common in males during prepubertal age but a well-established female preponderance is seen in adolescents and adults. The prevalence of migraine for children between 3 and 7 years is around 3%, and increases to 8% and 15% for those in the age-group 7–11 years and 11–15 years, respectively.

PATHOPHYSIOLOGY

Headache may arise from a variety of pain-sensitive structures, either intracranial (e.g., vascular sinuses, large vessels, dura surrounding these structures) or extracranial (e.g., skin, subcutaneous tissue, teeth). Although the brain, most of the dura, and ependymal are pain-insensitive; displacement, inflammation, injury or traction to the pain-sensitive structures may lead to a headache or facial pain. Most of the pain signals of head and face area are mediated through the trigeminal nerve and upper cervical nerves.

Migraine

Although recent research is advancing our knowledge of mechanisms of migraine, the exact pathophysiology remains unclear. A *trigeminovascular theory* is proposed. Migraine with aura is explained by a paroxysmal depolarization of cortical neurons. During the start of an attack, a *cortical spreading depression* (CSD) (a depression of spontaneous cortical electrical activity over the cerebral cortical surface) starts at the occipital pole of brain and moves anteriorly during the course of the attack at a rate of 2–3 mm/min. At the wavefront, neurons and glia depolarize, and there is also alteration of ion concentration between intracellular and extracellular compartments. These changes likely trigger the migraine aura and induce a reduction in posterior cerebral cortical blood flow. Multiple factors, including genetic predisposition, are proposed to be responsible for inducing the CSD. Cerebral ischemia is currently not considered to be important in the causation of migraine aura. The course followed by the CSD is independent of vascular territories and stops at the central sulcus.

The headache starts once the CSD reaches the pain-sensitive meningeal trigeminal fibers innervating the intracranial and dural blood vessels. The release of vasoactive substances such as substance-P and calcitonin gene-related peptide by the stimulation of trigeminal sensory neurons induces a neurogenic inflammation, which sensitizes the nerve fibers and leads to cutaneous allodynia. In migraine without aura, there are no demonstrable blood flow changes and mechanisms other than CSD are likely to be responsible, e.g., extracranial and intracranial arterial dilation.

Abnormalities in the metabolism and levels of various neurotransmitters, especially serotonin, have also been demonstrated in migraine. During an attack, the serotonin turnover decreases, whereas it is enhanced between attacks. 5-HT1, 5-HT2 and 5-HT3 are the serotonin receptors primarily involved in migraine pathophysiology. This also correlates with pharmacodynamics data as most drugs effective for acute management of migraine are agonists at the inhibitory 5-HT1_B and 5-HT1_D receptors, whereas propranolol and methysergide are antagonists to the excitatory 5-HT2 receptors.

Tension-type Headache

Previously considered to be primarily psychogenic, current research suggests a neurobiologic basis for TTH. The suggested mechanisms include genetics, muscle mechanisms, and central/peripheral pain sensitization. Peripheral pain mechanisms likely play a role in episodic TTH, whereas central mechanisms are more important in chronic TTH.

Genetics

Although familial occurrence of migraine is well-recognized, genetic studies do not support a Mendelian inheritance pattern for migraine. A high concordance rate among monozygotic twins in comparison to dizygotic twins has been reported, as has been the occurrence of similar subtype of migraine (with or without aura) among family members. Migraine thus appears to have a multifactorial inheritance probably leading to a genetic susceptibility. Familial hemiplegic migraine (FHM), a condition associated with prolonged neuro-deficit following a migraine headache, has shown a definite genetic inheritance pattern with subtypes described based on mutations in different genes viz., FHM1 with mutations in the *CACNA1A* gene (coding for a calcium channel) on chromosome 19; FHM2 with mutations in the *ATP1A2* gene (coding for a K/Na-ATPase) on chromosome 1; and FHM3 with mutations in the *SCN1A* gene (coding for a sodium channel) on chromosome 2.

Triggers

A number of intrinsic or extrinsic factors can trigger a migraine attack. The important triggers are stress, weather changes, fatigue, sleeplessness, hunger, and menstruation. Fasting has also been reported commonly as a trigger in Indian patients. Among Indian children, stress (both physical and emotional) and lack of sleep are the most common triggers.

Comorbid conditions Certain conditions occur commonly with headache and/or modify the headache characteristics. The more commonly recognized are obesity, epilepsy, sleep disturbances, allergy and sinus diseases, and psychological and emotional

disorders. Recognition of these conditions may help in deciding an appropriate therapeutic agent for headache (e.g., epilepsy, depression), and also assist in holistic management of the child.

CLINICAL FEATURES

Classification of the headache on the basis of temporal clinical pattern, as proposed by Rothner, is a useful clinical concept for initial evaluation. The five temporal patterns are: (1) Acute, (2) Acute recurrent, (3) Chronic progressive, (4) Chronic non-progressive, and (5) Mixed/comorbid headache. Each of these patterns suggests a distinct differential diagnosis.

Acute headache An acute headache in the neurologically normal child, although raising the possibility of serious intracranial pathology, is in the majority due to a viral infection such as upper respiratory tract infection or influenza. Migraine and serious neurological illness may also uncommonly present in this way. It can further be divided into generalized and localized headache. Acute localized headaches may be commonly due to sinusitis, dental pain, or temporomandibular joint dysfunction. However, in a febrile child with acute generalized headache, the need to rule out meningitis is paramount.

Acute recurrent headache It implies episodes of acute headache (irrespective of duration), separated by asymptomatic intervals, and is a pattern seen in migraine, TTH and cluster headache, though rare secondary causes such as intraventricular tumors (e.g., colloid cyst of the III ventricle) may present similarly. Majority of acute recurrent headaches in children presenting to a health setting are likely to be migraine.

Chronic progressive headache It is the pattern commonly associated with most of the serious intracranial diseases especially those with increased intracranial pressure, e.g., intracranial space occupying lesions, hydrocephalus, idiopathic intracranial hypertension. In a febrile child with such a history, chronic meningitis (especially tubercular) and brain abscess would be the important differentials.

Chronic nonprogressive headache It is a pattern of almost daily headache and usually a representation of chronic migraine. Other causes such as chronic sinusitis, ocular problems, hypertension, etc. may also need to be ruled out in this group.

Diagnosis of primary headache disorders of children rests principally on clinical criteria set forth by the International Headache Society (IHS), the International Classification of Headache Disorders, 3rd edition (ICHD-3). It is a comprehensive, predominantly evidence-based, hierarchical classification of headache disorders. An abbreviated form of this classification is provided in **Box 1**. The diagnostic criteria for children are not provided separately, although clarifications are provided, where appropriate. This classification system can be used both by the clinicians and the researcher, and brings much needed objectivity to headache diagnosis.

Migraine

Also called as common migraine, it is an acute recurrent type of headache disorder manifesting in attacks lasting 4–72 hours. Subtypes of migraine are listed in **Box 2**. Typical characteristics of the headache are unilateral location, pulsating quality, moderate or severe intensity, aggravation by routine physical activity and association with nausea and/or vomiting, and both photophobia and phonophobia **(Box 3)**. Migraine with aura, also called classical migraine, occurs in 15–30% of pediatric migraineurs. It is characterized by transient focal neurological symptoms that usually precede or accompany the headache.

BOX 1 Classification of headache disorders as per ICHD-3

Primary headaches:
- Migraine
- Tension-type headache (TTH)
- Trigeminal autonomic cephalalgias (TACs)
- Other primary headache disorders

Secondary headaches:
- Headache attributed to trauma or injury to the head and/or neck
- Headache attributed to cranial or cervical vascular disorder
- Headache attributed to nonvascular intracranial disorder
- Headache attributed to a substance or its withdrawal
- Headache attributed to infection
- Headache attributed to disorder of homeostasis
- Headache or facial pain attributed to disorder of the cranium, neck, eyes, ears, nose, sinuses, teeth, mouth or other facial or cervical structure
- Headache attributed to psychiatric disorder

Painful cranial neuropathies, other facial pains and other headache disorders.

BOX 2 Subtypes of migraine

- Migraine without aura
- Migraine with aura
  - Migraine with typical aura
  - Migraine with brainstem aura
  - Hemiplegic migraine
  - Retinal migraine
- Chronic migraine
- Complications of migraine
  - Status migrainosus
  - Persistent aura without infarction
  - Migrainous infarction
  - Migraine aura-triggered seizure
- Probable migraine
- Episodic syndromes that may be associated with migraine
  - Recurrent gastrointestinal disturbance
    - Cyclical vomiting syndrome
    - Abdominal migraine
  - Benign paroxysmal vertigo
  - Benign paroxysmal torticollis

Migraine headaches in children and adolescents are commonly bilateral and mostly frontotemporal. The duration of headache is shorter than that in adults, and for diagnostic purposes a minimum duration of 2 hours is sufficient. It is also more frequently associated with emesis. Both types of migraine patients may also have a premonitory phase hours or days prior to headache and a resolution phase after the headache. Symptoms include hyperactivity or hypoactivity, depression, food-craving, and fatigue.

Episodic Syndromes Associated with Migraine

Also called childhood periodic syndromes, these include cyclical vomiting and abdominal migraine (together labeled as recurrent gastrointestinal disturbances), benign paroxysmal vertigo, and benign paroxysmal torticollis **(Box 4)**. These disorders occur either in persons who have an increased likelihood to develop or those who suffer from migraine. It is important to rule out posterior fossa tumors, seizures and vestibular disorders before making a diagnosis of benign paroxysmal vertigo. Abdominal migraine is characteristically not accompanied by headache during the episode, and a diligent search for a gastrointestinal disorder is necessary before making this diagnosis.

BOX 3 ICHD-3 diagnostic criteria for migraine

Migraine without aura:
a. At least five attacks[1] fulfilling criteria b–d
b. Headache attacks lasting 4–72 hours (untreated or unsuccessfully treated)[2,3]
c. Headache has at least two of the following four characteristics:
   1. Unilateral location; 2. Pulsating quality; 3. Moderate or severe pain intensity; 4. Aggravation by or causing avoidance of routine physical activity (e.g., walking or climbing stairs)
d. During headache at least one of the following:
   1. Nausea and/or vomiting; 2. Photophobia and phonophobia
e. Not better accounted for by another ICHD-3 diagnosis

Migraine with aura:
a. At least two attacks fulfilling criteria (b) and (c)
b. One or more of the following fully reversible aura symptoms:
   1. Visual; 2. Sensory; 3. Speech and/or language; 4. Motor;
   5. Brainstem; 6. Retinal
c. At least two of the following four characteristics:
   1. At least one aura symptom spreads gradually over > 5 minutes, and/or two or more symptoms occur in succession; 2. Each individual aura symptom lasts 5–60 minutes;[4] 3. At least one aura symptom is unilateral;[5] 4. The aura is accompanied, or followed within 60 minutes, by headache
d. Not better accounted for by another ICHD-3 diagnosis, and transient ischemic attack has been excluded

Note: [1]*Individuals who otherwise meet criteria for migraine without aura but have had fewer than five attacks, should be coded probable migraine without aura.*
[2]*When the patient falls asleep during a migraine attack and wakes up without it, duration of the attack is reckoned until the time of awakening.*
[3]*In children and adolescents (aged under 18 years), attacks may last 2–72 hours (the evidence for untreated durations of less than 2 hours in children has not been substantiated).*
[4]*When, for example, three symptoms occur during an aura, the acceptable maximal duration is 3 × 60 min. Motor symptoms may last up to 72 hours.*
[5]*Aphasia is always regarded as a unilateral symptom; dysarthria may or may not be.*

BOX 4 ICHD-3 diagnostic criteria for episodic syndromes that may be associated with migraine

Cyclic vomiting syndrome:
a. At least five attacks of intense nausea and vomiting, fulfilling criteria (b) and (c)
b. Stereotypical in the individual patient and recurring with predictable periodicity
c. All of the following:
   1. Nausea and vomiting occur at least 4 times per hour;
   2. Attacks last ≥1 hour and up to 10 days;
   3. Attacks occur ≥1 week apart
d. Complete freedom from symptoms between attacks
e. Not attributed to another disorder[1]

Abdominal migraine:
a. At least five attacks of abdominal pain, fulfilling criteria (b–d)
b. Pain has at least two of the following three characteristics:
   1. Midline location, periumbilical or poorly localized;
   2. Dull or *just sore* quality;
   3. Moderate or severe intensity
c. During attacks, at least two of the following:
   1. Anorexia; 2. Nausea; 3. Vomiting; 4. Pallor
d. Attacks last 2–72 hours when untreated or unsuccessfully treated
e. Complete freedom from symptoms between attacks
f. Not attributed to another disorder[2]

Benign paroxysmal vertigo:
a. At least five attacks fulfilling criteria (b) and (c)
b. Vertigo[3] occurring without warning, maximal at onset and resolving spontaneously after minutes to hours without loss of consciousness
c. At least one of the following associated symptoms or signs:
   1. Nystagmus; 2. Ataxia; 3. Vomiting; 4. Pallor; 5. Fearfulness
d. Normal neurological examination and audiometric and vestibular functions between attacks
e. Not attributed to another disorder

Note: [1]*In particular, history and physical examination do not show signs of gastrointestinal disease.*
[2]*In particular, history and physical examination do not show signs of gastrointestinal or renal disease, or such disease has been ruled out by appropriate investigations.*
[3]*Young children with vertigo may not be able to describe vertiginous symptoms. Parental observation of episodic periods of unsteadiness may be interpreted as vertigo in young children.*

Tension-type Headache

Previously used terms for this disorder were tension headache, muscle contraction headache, psychomyogenic headache, stress headache, psychogenic headache, etc. It is a common headache disorder with a life-time prevalence of more than 70%, and occurs in 10–25% children. It is characterized by infrequent episodes of headache, typically bilateral, pressing or tightening in quality and of mild-to-moderate intensity, lasting minutes to days. The pain does not worsen with routine physical activity and is not associated with nausea, but photophobia or phonophobia may be present **(Box 5)**. The duration of headache in TTH is more variable and the pain is generally less severe than migraine.

Other Common Headaches

Chronic Daily Headache

Although not a standard diagnostic category, it is a commonly used clinical term. Chronic daily headache (CDH) is usually defined as headache occurring more than or equal to 15 days a month for more than or equal to 3 months. In children, it may be due to chronic migraine and/or TTH, new daily-persistent headache, or medication-overuse headache. Nearly 4% adults and 2% adolescents worldwide experience CDH. Around 1–5% children in school-based studies and around 25% in headache clinic-based studies are reported to have CDH. The importance of this condition is the frequent resistance to therapy, and the frequent occurrence of comorbid disorders including anxiety and depressive disorders, disorders of sleep, psychiatric disorders in the family, and other pain syndromes. Medication-overuse occurs concomitantly in about 30–35% adolescents with CDH.

BOX 5 ICHD-3 diagnostic criteria for tension-type headache*

a. At least 10 episodes of headache occurring on < 1 day/month on average (< 12 days/year) and fulfilling criteria (b-d)
b. Lasting from 30 min to 7 days
c. At least two of the following four characteristics:
   1. Bilateral location
   2. Pressing or tightening (nonpulsating) quality
   3. Mild or moderate intensity
   4. Not aggravated by routine physical activity such as walking or climbing stairs
d. Both of the following:
   1. No nausea or vomiting
   2. No more than one of photophobia or phonophobia
e. Not better accounted for by another ICHD-3 diagnosis

*Note: *Headache occurring on 1–14 days/month on average for >3 months (≥12 and <180 days/year) with similar characteristics is labeled as frequent episodic tension-type headache.*

Post-traumatic Headache

Post-traumatic headache (PTH), a headache attributed to head and/or neck trauma, is the most common secondary headache with the prevalence of chronic PTH varying from 3.2% to 6.8% in children with head injury. It is defined as headache developing within seven days after head trauma (or after regaining

consciousness following head trauma) and resolving within 3 months or persisting beyond that time for being labeled as acute and persistent PTH, respectively. A late onset PTH starting after 7 days has also been described. The most common headache pattern is either episodic TTH or migraine without aura. Severity of head injury has not been found to correlate with severity or duration of PTH. Prognosis of PTH in pediatric population has been shown to be good with headache resolving over a variable period of time in majority. The pathophysiology of PTH is not well elucidated, though precipitation of primary headache in predisposed individuals is suggested.

APPROACH TO DIAGNOSIS

The crux of evaluation for a child with headache is a good history, which classifies the temporal pattern and guides to the likely diagnosis, and a thorough clinical examination that helps in ruling out underlying systemic diseases or neurological disorders as a cause of the headache **(Box 6)**. The history should be obtained directly from the adolescent patient, and with parental inputs in the younger patients.

Clinical Evaluation

History-taking in a child with headache is similar to that in any other disease, except for two caveats. It is difficult for children (even adolescents) to accurately describe the quality of pain, because of infrequent prior pain exposure and lack of appropriate vocabulary. Secondly, asking young children (<10 years) about the frequency or duration of headache is rarely going to provide reliable responses; parental reports should be used for confirmation. Many children with recurrent headache remain unclassifiable (or classified in probable categories) because of inability to communicate information regarding pain quality and severity, associated symptoms, and aggravation by activity. Thus, rigid adherence to diagnostic criteria may not be a beneficial approach in office practice.

Factors to be assessed in history include: onset, location and duration of headache, quality of pain, associated features (including aura and triggers), disability, school absences, drug history, family history, history of head injury, and comorbidities. Many drugs and food additives are known to cause migraine-like headaches, and need to be specifically ruled out. Common amongst these are analgesics (when over-used), carbamazepine, nitrites (present in cured meat), monosodium glutamate (MSG) in Chinese food, and caffeine. However, little published evidence is available for food items as the sole precipitants of headache, and should only be considered when each exposure leads to symptoms.

BOX 6 Red flags in headache evaluation

Symptoms:
• Chronic progressive headache
• Recent change in headache character or frequency
• Recent onset sudden severe headache (<1 month duration)
• Thunderclap headache
• Occipital location of headache
• Fever or increased temperature
• Retinal hemorrhages
• Neck rigidity
• Headaches accompanied by seizures

Signs:
• Fundal changes
• Abnormal neurological examination
• Gait abnormalities
• Altered sensorium

Caffeine intake may be evident (as with coffee/colas/tea) or unrecognized, in the form of carbonated drinks or energy drinks (many of which may not have a cola color but carry significant amounts of caffeine), and may cause a *caffeine-withdrawal headache*. The headache is usually a dull frontotemporal headache an hour or more after the last use. Treatment is by cessation of caffeine intake.

A detailed physical and neurological examination is crucial to exclude underlying disease processes. Fundus examination for papilledema may help to identify raised intracranial pressure, and is an important component. Blood pressure measurement with an appropriate-sized cuff is essential part of headache evaluation as underlying hypertension may be a cause of headache. A sudden rise in systolic BP causes explosive throbbing headache. Chronic hypertension may cause low-grade occipital headache on awakening that diminishes as the child gets up and begins activity, or frontal throbbing headache during the day. However, most children with chronic hypertension are asymptomatic.

Routine ophthalmological evaluation is unnecessary in recurrent acute headache, but may be indicated in a child with chronic headache who has never had an ophthalmological evaluation. If done, such an evaluation should include both refraction and an orthoptic evaluation. Dull aching pain behind the eyes that is quickly relieved when the eyes are closed, is usually seen in those with latent disturbance in convergence.

Routine ENT examination is also not indicated, unless recurrent acute headaches are coincidental with a viral syndrome, or localized headache is present with sinus tenderness. In case of frontal or maxillary sinusitis, tenderness is directly elicited over the sinus whereas with ethmoidal or sphenoidal sinusitis, deep midline pain behind the nose is characteristic. Radiological evidence of sinusitis should not be used to explain recurrent headaches, as sinusitis is not an uncommon finding during radiological examination for other diseases.

Pain Measurement

This is needed to determine, if treatment is necessary and to see the effect of treatment. Self-report is the most common measure of pain obtained from children, adolescents and adults. Children experience difficulty in describing pain using verbal language, but do better by matching with pictorial representation of emotions. Thus, asking children to match their experiences of pain with appropriate pictures of children's facial expressions are often used, e.g., Faces scale where children are asked to point to the face that best shows how much pain they are currently experiencing. The visual analogue scale (VAS) consists of a horizontal line, 100 mm in length which is anchored by word descriptors at each end. Marking occurs where current pain perception lies. VAS score is measured by measuring in millimeters from left hand end of the line to the point that the patient marks.

Headache diary The role of headache diary in pediatric pain conditions has a long tradition and significant evidence-base. A headache diary, maintained by the patient (with parental help in younger children), helps in documenting the headache duration, severity, associated factors, disability and medication-use. It also helps the child in taking control of his disease, and may help in objectively assessing the response to treatment.

Disability Assessment

Disability induced by migraine can be measured with question-naires developed and validated in migraine patients with good psychometric properties, such as MIDAS and HIT-6. WHO-DAS 2 is a general disability tool which was developed specifically for headache patients. PedMIDAS is a widely used tool to assess migraine disability in pediatric and adolescent patients. It has been

tested and validated for ages 4–18. It consists of seven questions for which scores are given based on the disability over the previous 3 months. Disability is graded into: No (score <11), mild (score 11–30), moderate (31–50), and severe (> 50) disability.

Investigations

Laboratory evaluation in a child with headache is guided by the clinical context; the plan of investigations will be different for a child with recurrent acute headache as compared to a clinically ill child being evaluated in the emergency room. For children with recurrent headaches, none of the routine hematological or biochemical studies has been found to be of any clinical utility. On the other hand, in a child with headache in association with features suggestive of an underlying neurologic or systemic condition, further laboratory studies may need to be ordered based on the suspected disorder. The EEG is not indicated for the evaluation of recurrent headaches. Similarly, CSF examination is also of limited value in the routine evaluation of headaches in children. However, it may be important when one is suspecting an underlying CNS infection or idiopathic intracranial hypertension.

Neuroimaging Around 15% children with recurrent headache are reported to have abnormalities on neuroimaging, though more than 80% of these are incidental or not requiring specific management. Most studies have shown that even though a significant minority of children with recurrent headaches has a surgically correctable lesion or medically amenable condition on neuroimaging, almost all had an abnormal neurological examination, e.g., papilledema, gait abnormalities, abnormal eye movement, etc. A practice parameter of the American Academy of Neurology also does not recommend neuroimaging in children with recurrent headache and a normal neurological examination. It may be considered when there is recent onset of severe headaches or when there is a change in the type or quality of the headache, and rarely if there is excessive parental concern.

MANAGEMENT

Management of headache encompasses both treatment of an acute attack and prevention of recurrence of further attacks. In addition, comorbidities need to be identified and managed, and biobehavioral interventions initiated to minimize the effects of the attacks. These therapeutic goals need to be shared with the patient and the family to ensure adherence to the management plan. The drugs used and the doses are detailed in **Table 1**. The hierarchy of management in the Indian setting should be home-based management with over-the-counter analgesics (and trigger avoidance), primary care-based management with prescription analgesics and common prophylactic drugs, specialist-supervised management with triptans and other prophylactic drugs.

Biobehavioral therapy or the incorporation of adherence, education, lifestyle adjustment, and coping skills is essential to the management of pediatric migraine. A regular and healthy lifestyle needs to be promoted including regular meals and a balanced diet (without meal-skipping), adequate hydration (and reduced intake of caffeine-containing beverages), regular exercises, sufficient sleep with regular sleep habits, and avoidance of triggers.

Migraine

Acute Treatment

Acute treatment aims at rapid and complete relief of headache and associated manifestations with early return to normal functioning. The drugs used fall in two categories, viz., nonspecific analgesics (acetaminophen and NSAIDs, especially ibuprofen) and migraine-specific agents (triptans). A practice parameter on management of pediatric migraine recommended ibuprofen as effective and paracetamol as probably effective for acute treatment. NSAIDs such as ibuprofen are effective when used in adequate doses early in the attack. In case of absence of complete response, triptans may be more effective. Triptans are 5-HT receptor agonists and the maximum pediatric experience is available for sumatriptan. In

Table 1 Commonly used drugs for management of migraine in children

Drug	Dose	Comments
Acute treatment (Avoid overuse of all acute medications)		
Paracetamol	15 mg/kg/dose, 6–8 hourly	Less effective than ibuprofen
Ibuprofen	7.5–10/mg/kg/dose, 8-hourly	
Triptans		Serotonin symptoms and vascular constriction (reduced somewhat with adequate hydration) are the main side effects
Sumatriptan	10 mg nasal, repeat once only after 2 hours, if needed 6 mg SC	
Almotriptan	12.5 mg	
Zolmitriptan	2.5 mg oral, 5 mg nasal	
Rizatriptan	5 mg (< 40 kg), 10 mg (≥ 40 kg)	
Prochlorperazine	0.15 mg/kg IV	More effective when combined with ketorolac and hydration
Preventive treatment		
Propranolol	2–3 mg/kg/day TDS	Begin at lower dose (~10 mg/day) and increase weekly, max dose 60 mg
Flunarizine	5–10 m/day HS	Start with 5 mg and increase in case of nonresponsiveness
Amitriptyline	1 mg/kg/day HS	Start at low dose, increase by 0.25 mg/kg every 2 weekly; initial side effects gradually subside
Cyproheptadine	0.2–0.4 mg/kg/day BD	Side effects reported less commonly in children
Antiepileptics		Usually half of epilepsy dose suffices
Sodium valproate	15–30 mg/kg/day, BD or TDS	Begin at 5 mg/kg/day, increase by 5 mg/kg 2-weekly
Topiramate	100–200 mg divided BD	Increase slowly over 3–4 months

Abbreviations: D, day; BD, twice-a-day; TDS, thrice-a-day; HS, single night-time dose; IV, intravenous; SC, subcutaneous injection.

the AAN practice parameter, among the triptans, only sumatriptan nasal spray was found to have sufficient evidence for acute management of migraine, and that too only in adolescents. The evidence in favor of subcutaneous or oral triptans was found to be insufficient. However, more data is now available on oral triptans and zolmitriptan, almotriptan, and rizatriptan have shown efficacy in pediatric migraine. Of these only almotriptan is FDA approved for children. Management of the migraine when above drugs fail and the child presents acutely to healthcare is not well-delineated. However, dopamine-antagonists (prochlorperazine) with intravenous NSAIDs may be effective. Intravenous dihydroergotamine may also be used for more severe cases.

To avoid medication overuse, nonspecific agents should be used less frequently than 2–3 times per week and triptans not more than 6 times per month. Use of other NSAIDs such as diclofenac or ketorolac can also be tried. Indomethacin has also been found useful, especially for stabbing headache and paroxysmal hemicranias, though the risk of side effects is higher. Domperidone (0.2 mg/kg/dose 8-hourly) or metoclopramide (0.1 mg/kg/dose 8-hourly) promote gastric emptying and normal peristalsis and may have some use in migraine with prominent vomiting, though pediatric evidence is not available. Compound preparations containing both analgesic and antiemetic (e.g., paracetamol and metoclopramide) are available for adults and convenient, but the relative dose of the individual drugs for pediatric patients is usually inappropriate. Combinations of two analgesics or codeine with paracetamol are available and used in adults, but not much information is available for children. Similarly, combining triptans and NSAIDs is effective in adults but pediatric data is lacking.

Preventive Treatment

Although no guidelines are available on when to start preventive therapy, it should be considered when migraine attacks are either too frequent (≥ 3/month) or too disabling (PedMIDAS score > 30, or causing frequent school absences). This decision needs to involve both the patient and the parents, and the goals (decrease headache frequency to < 1–2/month and disability to PedMIDAS score < 10) communicated to them. Preventive therapy should be used for a 4–6 month period before being gradually tapered, preferably at a time of low-stress, e.g., school breaks. Changing preventive therapy should be considered, if there is a lack of efficacy over a 6–12 week period, and/or unacceptable side effects appear. Quite a few drugs have been tried for preventive therapy but the following five are the most commonly used in pediatric patients (listed in a sequence of personal preference).

Among the antihypertensive agents, propranolol (a non-selective beta-blocker) and flunarizine (a calcium-channel blocker) are the two drugs commonly used in children. The longest clinical experience has been with propranolol, though high-class evidence for its efficacy is sketchy. However, used at 2–3 mg/kg/day in 2–3 doses, it has a good response. There is a need to rule out asthma and cardiac conduction disorders prior to starting the drug, and side effects include postural hypotension and depression. Children on beta-blockers should be cautioned against participation in competitive sports and rigorous physical activity. *Flunarizine* likely exerts its effect through selective inhibition of vasoactive substances on cerebrovascular smooth muscles. Drowsiness and weight-gain are the side effects, though once-a-day dosage is an advantage for school-going children. It was the only drug considered to be probably effective in the AAN practice parameter for treatment of migraine in children.

Although a variety of antidepressants are used for migraine prophylaxis, pediatric data for their use is lacking. The anti-depressant most frequently used in children for this purpose is *Amitriptyline*. Cardiac conduction abnormalities, sedation and anticholinergic side effects are the common problems with its use; a single-dose at bedtime is the preferred usage.

Cyproheptadine use in migraine prophylaxis, especially in children, has a long history. Good quality studies are lacking, but a dose of 2–8 mg/day at bedtime appears effective. The side effects of sedation and increased appetite are seen less frequently in children, as compared to adults. The utility of this agent is more for the management of cyclical vomiting syndrome, and also in migraineurs with prominent gastrointestinal symptoms.

As the pathophysiology of migraine has veered toward a primary neuronal initiation and a CSD, *antiepileptic drugs* are increasingly being evaluated and used as preventive therapy. Of these valproic acid and topiramate are the most commonly used in children, and also have reliable evidence of efficacy. Side effects of both these drugs are similar to those when used in epilepsy.

Other drugs like pizotifen, gabapentin, levetiracetam and clonidine have some evidences of efficacy and are in clinical use, but have not been detailed due to insufficient evidence, and infrequent use at our center. Nutraceuticals such as coenzyme Q_{10}, riboflavin and magnesium may have some roles in prophylaxis, but clear evidence of benefit is still awaited.

Tension-type Headache

Management of tension-type headache (TTH) in children suffers from lack of robust evidence for efficacy of various therapies. Due to the long duration and frequency of TTH, there is also a higher possibility of analgesic-overuse in this disorder. Moreover, psychosocial variables may too often be blamed as an etiological factor for TTH in children, probably a throwback to the *tension* headache days. However, if present, psychological factors need to be addressed.

Nonpharmacologic approaches such as biofeedback (either electromyographic or skin-temperature based), relaxation training, and psychological interventions have the benefit of avoiding or reducing pharmaceutical use and its related cost and side effect issues. However, availability of facilities and adherence to lifestyle management may be challenging.

Simple analgesics and NSAIDs are the first-line drugs for the acute management of TTH in children and adolescents. Since TTH is not associated with gastroparesis, these drugs might work better here than in migraine. Although the evidence for the utility of pharmacological preventive therapy in TTH in children is limited, the most widely used drug for this purpose is amitriptyline.

OUTCOME

Treatment of pediatric headache is generally effective, with most having improvement in headache characteristics, with more than 90% having sustained headache improvement as late as 5 years after appropriate diagnosis and management. Around two-thirds of migraine patients will have attacks throughout life, although a majority is intermittently free from them for long periods, or partially relieved with appropriate management. Our experience has been that after an appropriate diagnosis and detailed management plan has been made, majority of children evaluated for recurrent headache will require 2–3 additional visits, before the headache subsides or there is sufficient reduction in severity and disability so that home management suffices. Subsequent, follow-up visits can be on as needed basis or 6-monthly.

Parents of a child presenting with recurrent headache need both management of headache and also reassurance about absence of serious intracranial pathology. The cornerstone of evaluation in headache patient is history and physical examination, which occasionally aided by investigations, help in distinguishing primary and secondary headaches and initiating appropriate management. The role of a headache diary in the initial evaluation, and the need for a regular lifestyle during the management phase

needs to be recognized more widely. However, it should be remembered that only a minority of acute headache attending the emergency are due to serious intracranial conditions.

IN A NUTSHELL

1. Headaches are common in children and adolescents.
2. A good history and thorough examination is sufficient for accurate diagnosis in majority of children with recurrent headaches.
3. Routine eye examination or ENT work-up is not required for recurrent acute headaches.
4. A chronic progressive headache is an ominous sign and should be emergently evaluated.
5. Neuroimaging is infrequently required for headache evaluation.
6. Decide goals of management and communicate the same to the patient and parents.
7. Holistic management of primary headache should address lifestyle changes and avoidance of triggers, in addition to pharmacotherapy.

Chapter 42.23
Movement Disorders
Debabrata Ghosh

Movement disorders comprise a group of heterogeneous conditions in which the primary symptom is a form of involuntary movement. In this chapter, primary focus is on the approach to the diagnosis and management of involuntary movements in children and brief discussion of some common disorders with involuntary movements. Based on the etiology, movement disorders may be classified as *Primary* (idiopathic or genetic), when there is no apparent structural brain abnormality on magnetic resonance imaging (MRI), or, *Secondary* (symptomatic), when there is a structural brain damage. For a complete evaluation of a child with a movement disorders, a 4-step system is followed:

- *Step 1:* Characterization of the 'abnormal involuntary movements'.
- *Step 2:* Associated neurological and/or systemic features.
- *Step 3:* Complete diagnosis of the *movement disorder*, comorbidities, and, etiology.
- *Step 4:* Management: medical and surgical.

Based on the type, movement disorders are divided into two basic categories: *hypokinetic* and *hyperkinetic*. Hyperkinetic disorders, manifest with either single or varying combination of *abnormal involuntary movements* such as dystonia, chorea, athetosis, ballism, tics, myoclonus, tremor, and stereotypy. Hypokinetic or bradykinetic (reduced movement) disorders are uncommon in childhood. Parkinson's disease and Parkinsonism, primarily adult disorders comprise the most of all cases of the hypokinetic or bradykinetic disorders. A few childhood movement disorders which may have Parkinsonian features include: a) early onset Parkinson's disease, b) Wilson disease, c) Juvenile Huntington disease, and d) Pantothenate kinase associated neurodegeneration (Hallervorden-Spatz disease).

The anatomical and physiological basis for the movement disorders and their pathogeneses are still not elucidated. Broadly stating, all movement disorders happen due to either structural or functional alteration in any of the anatomical structures comprising basal ganglia and/or its connection **(Fig. 1)**. Basal ganglia comprise of the following neuroanatomical structures—sensory or receptive or afferent limb: putamen, caudate nucleus (together called as striatum due to its striate appearance); efferent limb: globus pallidus, which is again divided into pars externa (GPe) and pars interna (GPi); substantia nigra, divided in two parts, pars compacta (neurons from here project to putamen), and pars reticulata (functionally an offshoot from GPi); subthalamic nucleus modulates the input to GPi. Thalamus, though not classically considered as part of the basal ganglia, but part of the thalamus forms an integral part of the corticostriatopallido-thalamic cortical circuit carrying the information from GPi to various areas of cortex. The basis for any of the involuntary movement lies in the dysfunction of the above circuit. There are multiple parallel pathways which subserve various specific functions still to be completely understood.

APPROACH TO MOVEMENT DISORDERS IN CHILDREN

In approaching a child with movement disorders the first step is a clear definition and understanding of the phenomenology of the underlying abnormal involuntary movements. Involuntary movements are not always describable, so observation of the movement is very vital to the diagnosis. Visual recognition through direct observation or review of the video recording is an excellent tool to supplement history from parents, caregivers and the patient him/herself. Home video is a good option, more so for the paroxysmal disorders. The event may not occur during the office visit. Patient's birth history, early development, previous illness, history of exposure to drugs and toxins, as well as social and family history are important. Description of semiology of the involuntary movements should include age of onset, course, types of movement, focality, timings, triggers, suppressibility, progression, and vocalization, impact of various activities on the involuntary movement and the impact of involuntary abnormal movements on various activities of life, sensory trick, self-stimulation, and self-mutilation. Changes in the movement in relation to awake/sleep state may give clue towards recognition of the involuntary movement. How the movement changes in supine, sitting, standing posture, and during walking may help in narrowing down the list of differential diagnoses.

The relationship of sleep and involuntary movements is very complex. Some of them may appear, some may persist, and some may disappear during sleep. Dystonia is a classic example of an involuntary movement which disappears during sleep. So the children with acute dystonic crisis are sedated for a shorter period to prevent muscle breakdown or severe pain/spasm/distress. **Box 1** shows a list of conditions associated with involuntary movements which occur or persist during sleep. For more detailed evaluation of these disorders, polysomnography may sometimes be indicated.

It is worthwhile again to reiterate that involuntary movements are merely physical symptoms/signs, not a diagnosis, and more often than not they do not occur always in pure form. A single disorder may have several types of involuntary movements of varying age of onset. Huntington's disease may produce akinetic rigid state in childhood but predominantly chorea in adults.
Figure 1 Basal ganglia anatomy and its connection forming multiple parallel *Cortico-Striato-Pallido-Thalamo-Cortical* circuits important for various abnormal involuntary movements
Abbreviations: ext, exterior; int, interior; p.c., pars compacta; p.r., pars reticulata

---

BOX 1 Common abnormal involuntary movements in sleep

- Hypnic jerk (Benign nocturnal myoclonus)
- Bruxism (Tooth grinding)
- Rhythmic movement disorder
- Restless leg syndrome
- Palatal myoclonus/tremor
- Spinal myoclonus
- Paroxysmal hypnagogic dyskinesia
- Nocturnal myoclonic jerk associated with hyperekplexia.

Patients with dentatorubralpallidoluysiyan atrophy (DRPLA) may present with progressive myoclonic epilepsy with ataxia in a child and with chorea and dementia during adulthood. Primary myoclonus dystonia patients have both myoclonus and dystonia as the clinical feature. Symptomatic dystonia in children with cerebral palsy may coexist with spastic quadriparesis. There is also frequent co-occurrence of tremor or choreoathetoid movements in children with cerebral palsy. Symptomatic dystonia often manifests years after the inciting injury to the brain thus giving a false impression of another new onset disorder. The evaluating physician should bear this fact in mind when facing a situation when dystonia complicates the course of spastic quadriplegic cerebral palsy.

APPROACH FROM THE PERSPECTIVE OF ABNORMAL INVOLUNTARY MOVEMENT

There is paucity of data regarding prevalence of various types of abnormal involuntary movements in children. Personal observation of the author (2006–2009) in a tertiary care hospital in United States of America and the experience from another tertiary care center at Spain has been summarized in **Box 2**.

SPECIFIC ABNORMAL INVOLUNTARY MOVEMENTS

Dystonia

It is characterized by a forceful muscle contraction producing intermittent or sustained abnormal posturing or twisting of the body. It can be classified according to distribution in various body areas—focal (single body region such as tongue, hand, leg); segmental (involvement of a segment or region such as neck, face and neck, trunk, the whole limb); multifocal (multiple noncontiguous body areas), hemidystonia (one half of the body), and generalized (any focal and adjoining segmental or more body areas). Etiologically, dystonic disorders are classified broadly as

primary and secondary. In children, the most common primary dystonia is generalized, whereas in adults, focal/segmental. Common causes of dystonia in the pediatric age group are listed in **Table 1**. Paroxysmal abnormal involuntary movements are described separately.

Dystonia can be fixed or variable, and is often associated with irregular tremor, also called as dystonic tremor. The severity of dystonia is worse on attempted use of the affected body part(s), and it improves on rest. Dystonia nearly disappears during deep sleep. This fact is utilized in making the diagnosis of dystonia mimickers. If the posture or severity of the muscle contraction is unchanged or worse in sleep, the possibility of spasticity, contracture, psychogenic dystonia (not actual sleep), or dystonia as a manifestation of seizure, mostly of basal frontal origin, are more likely. The other characteristic feature of dystonia is co-contraction of agonist and antagonistic muscles, thus precise useful function is not possible. The muscle strength in primary dystonia is preserved; in fact individual muscles are stronger, and often work-hypertrophied. In spite of preserved strength of individual muscles, the precise control over the muscles is lacking. On attempted use of the limb for any purpose, the abnormal posture/twisting gets worse. The other feature of dystonia is overflow involving contiguous muscles, sometimes, there may be mass movement of the whole affected limb on attempted use of the limb. Anxiety/stress may bring on dystonia or may make dystonia worse, relaxation helps, as also sleep as mentioned earlier. The body or body parts may be so convoluted that the child may be curled up in bed all the time, unable to sit, stand, or walk. It may be difficult to use the wheelchair, dress/undress, put the shoes on, using orthotics. The persistent dystonic posturing may produce contracture and associated bony or joint changes. Dystonic muscles may be extremely painful as persistent involuntary muscle hyperactivity may increase the demand for oxygen or other metabolites, even normal blood flow may not be adequate thus there may be relative hypoxemia or metabolic insufficiency.

Dystonia, when generalized, severe, and progressive, and more so after a psychological or physical stress of infection or pain anywhere in the body, may be severe and persistent, not responding to the usual oral medication. This condition is then called as dystonic storm. During this storm, the child may have severe pain, and muscle breakdown producing rhabdomyolysis, and even renal failure. Dystonia is a well-known cause for elevated serum creatine phosphokinase (CPK). Dystonic storm has to be managed at a hospital, preferably at intensive care unit with sedation, hydration, monitoring renal and other systemic function, there may be a short-term need for general muscle relaxant and paralytic along with ventilation support.

BOX 2	Types of common abnormal involuntary movements in children	
	Alvarez, Aicardi 2001 **(n = 684)**	**Cleveland Clinic Series 2009** **(n = 434)**
Tics	39%	26%
Dystonia	24%	28%
Tremor	19%	8%
Stereotypy	0%	14%
Chorea	5%	8%
Myoclonus	2%	4%
Psychogenic	0%	5%
Ataxia	?	3%

Table 1 Common causes of dystonia in children

Congenital and developmental	Dystonic cerebral palsy, congenital brain malformation, basal ganglia stroke, benign dystonia of infancy, paroxysmal torticollis in infancy, dyspeptic dystonia with hiatus hernia
Infectious diseases	Viral encephalitis including Japanese B encephalitis, West Nile
Metabolic causes	Wilson disease, Dopa responsive dystonia, GM2 gangliosidosis, phenylketonuria (PKU), mitochondrial disease, glutaric aciduria, homocystinuria, tyrosinemia, neuronal ceroid lipofuscinosis, Lesch-Nyhan Syndrome
Medication/Toxin-induced	*Antipsychotic/Antiemetic:* Haloperidol, tetrabenazine, reserpine, phenothiazines, metoclopramide. *Antiepileptic:* Carbamazepine, phenytoin. *Toxic:* Methanol, carbon monoxide, manganese.
Hereditary/Degenerative disorders	Genetic dystonia (DYT 1,2,3,4,5,6,7,8,9,10,11; *DYT 1:* Torsin A mutation, *DYT 5:* Dopa responsive Dystonia, *DYT11:* Primary Myoclonus Dystonia), Rapid onset dystonia parkinsonism, pantothenate kinase associated Neurodegeneration (Neuronal brain iron accumulation—NBIA-1 or Hallervorden-Spatz disease); Ataxia telangiectasia, Huntington disease (Juvenile onset or Westphal variant), neuroacanthocytosis.
Psychogenic	Fixed, variable or episodic

Myoclonus

It is characterized by sudden shock-like forceful muscle contraction. Myoclonus may result from pathology in the cerebral cortex, subcortical region or spinal cord. Clinical evaluation should include the onset, time course, drug or toxin exposure, history of seizures, past and current medical problems, perinatal history, mental status changes, and family history. The neurological examination should include movement distribution, temporal profile, and activation characteristics. Distribution can be focal, multifocal, segmental or generalized. The temporal profile may be rhythmic (as in palatal myoclonus); irregular and unpredictable (as in propiospinal myoclonus). From the activation stand point, myoclonus may be at rest (spontaneous), or induced by various stimuli (reflex myoclonus), induced by voluntary movement (action myoclonus). Myoclonus is more often positive (muscle contraction), and rarely negative (loss of muscle tone/activity). The best example of negative myoclonus is asterixis, commonly noticed in diffuse encephalopathy due to advanced hepatic, renal, respiratory failures, or barbiturate poisoning. Etiologically, myoclonus can be classified into physiologic or pathologic.

Sleep myoclonus is a common physiological myoclonus. It happens mostly during early sleep, affecting any of the limbs, and sometimes even the whole body. Severity may vary from brief leg or arm jerk to whole body jerk. Sleep myoclonus is benign, usually starts during infancy and gets better in early childhood. The close differential is seizure, more so when it affects newborn babies. Video-EEG monitoring is commonly done to rule out seizures and thereby allay the anxiety among parents and pediatricians.

Pathologic myoclonus may be epileptic or nonepileptic. Epileptic myoclonus (i.e., myoclonic seizures, with epileptiform discharges on EEG) is a part of many epileptic syndromes (e.g., juvenile myoclonic epilepsy) and degenerative disorders (progressive myoclonic epilepsy); and is discussed in the chapter on seizures and epilepsy. Pathological nonepileptic myoclonus may further be classified as primary (myoclonus occurs as a primary symptom) and secondary (myoclonus occurs secondary to some other cause). Hyperekplexia is a form of nonepileptic myoclonus, which is stimulus sensitive, i.e., there is an exaggerated startle response. Any stimulus, tactile, auditory, or visual provokes an exaggerated startle with head flexion and extension and abduction of arms. The child may have frequent and persistent stiffening. **Table 2** shows common causes of pathological myoclonus in pediatric age group.

Myoclonus generally improves or disappears during sleep except the *palatal* and *segmental myoclonus*. This fact should be borne in mind to make a definitive diagnosis of the above. Palatal myoclonus in children is somewhat different from that in adults. There are two distinct variants of palatal myoclonus in children, one type, more common, is a developmental phenomenon noticed at about 4–5 years of life, this is usually benign and self-limiting with complete disappearance by the teen age years. The other variant is akin to that in adult, associated with hypertrophy of inferior olive, and persists throughout life with poor prognosis. Not uncommonly myoclonus may be psychogenic.

Chorea

This consists of irregular, unpredictable, brief, jerky, arrhythmic, semi-purposive movements that fleet randomly from one part of body to another. Chorea is characterized by or associated with hypotonia, *pronator sign* manifesting as pronation of forearm when arms are outstretched in front, motor impersistence manifesting as *milkmaid* grip, and *Jack in the box* tongue when asked to protrude the tongue out. Chorea also produces *hung up* ankle jerk due to superimposition of chorea during the elicitation of the deep tendon reflex. It may also cause *halted speech* due to superimposition of chorea involving the articulating muscles. There are several causes of chorea. Again the clinician must carefully consider the history, relation to preceding infection, exposure to medication, familial occurrence, age of onset and manner of progression. Hemichorea may result because of vascular causes. Benign hereditary chorea typically begins in childhood with a slow progression and very little or no cognitive change. Huntington's disease in adults is always associated with chorea, but presents with akinetic rigidity in children, usually with severe mental changes, seizures, and rapid progression. *Ballismus*, a forceful flinging movement, can be considered as violent chorea, with classic correlation with a lesion at subthalamic nucleus. *Athetosis* is the distal slow writhing, fluid, dancing type of movement, often associated with chorea. Athetosis can also be considered as distal dystonia affecting primarily the distal fingers/hands. Pseudoathetosis is a term used sometimes to describe involuntary movements mimicking athetosis but caused by the loss of proprioceptive input from the affected limb as is noticed sometimes in severe demyelinating polyneuropathy as a part of *deafferentation* syndrome when the brain does not get timely signal from periphery about the position of the limbs in space. **Table 3** summarizes common causes of chorea encountered in children.

Benign hereditary chorea may affect the child variably. Most of the affected individuals live normal life with minimal chorea which does not progress. The chorea is the only abnormality in

Table 2 Common causes of pathological myoclonus in pediatric age group

Primary	Essential myoclonus, primary myoclonus dystonia
Toxic	Lead, CO, mercury, toluene encephalopathy; tricyclics, lithium, selective serotonin reuptake inhibitor, monoamine oxidase inhibitors; antibiotics like penicillin, cephalosporins, quinolones; general anesthetics; anticancer drugs.
Traumatic	Intracerebral hemorrhage, subdural hematoma, diffuse axonal injury.
Vascular	Cerebral venous thrombosis; *Vasculitis:* Systemic or central nervous system.
Metabolic and endocrine	Hepatic failure, hypoxic encephalopathy, hypo- or hyperglycemia, hyponatremia, Wilson disease, uremia, mitochondrial encephalopathy, Gaucher disease, sialoidosis, gangliosidosis, neuronal ceroid lipofuscinosis (NCL), organic acidurias, urea cycle defect.
Degenerative	Lafora body disease, Huntington's disease, PKAN (Hallervorden-Spatz), Ramsay-Hunt syndrome, SSPE (Subacute sclerosing panencephalitis).
Infectious/ postinfectious	Meningitis, acute and chronic encephalitis, acute disseminated encephalomyelitis (ADEM), subacute sclerosing panencephalitis (SSPE).
Epileptic	Myoclonic epilepsies—Infantile, Juvenile; Progressive myoclonus epilepsies such as Unverricht-Lundborg disease, Lafora body disease.
Miscellaneous	Opsoclonus-Myoclonus, Palatal myoclonus, segmental myoclonus.

Table 3 Common etiologies of chorea in children

Congenital	Cerebral palsy (including kernicterus), birth trauma, congenital malformations
Genetic	Benign hereditary chorea, Fahr's disease, Friedreich ataxia, pantothenate kinase-associated neurodegeneration (Hallervorden-Spatz disease), ataxia telangiectasia, Huntington disease, neuroacanthocytosis, Rett syndrome.
Metabolic	Wilson disease, mitochondrial disorders, Lesch-Nyhan syndrome, gangliosidosis, Neimann-Pick disease Type C, organic acidurias
Drug or toxin-induced	Neuroleptics including antiemetics, anticonvulsants, stimulants, isoniazid, carbon monoxide, oral contraceptives, Lithium, alcohol, propofol, tricyclic antidepressants, manganese.
Neoplastic	Brain tumors
Traumatic	Traumatic brain injury, burns encephalopathy in children
Systemic Condition	SLE, Henoch-Schönlein purpura, malnutrition, hypoglycemia, hypoparathyroidism, hyperthyroidism, Postopen heart surgery (Postpump chorea), chorea gravidarum.
Infectious	Post-streptococcal (Sydenham chorea), tubercular meningitis, neurosyphilis (congenital), viral encephalopathy, encephalitis, ADEM.

the affected child, behaves like static encephalopathy, many are misdiagnosed as cerebral palsy. It runs in family in an autosomal dominant fashion, there is mutation in the *NKX2.1* gene encoding for a homeobox protein. The course is usually benign, may not require any specific treatment. Avoiding the use of anticholinergic medication help these children as chorea can get worse with anticholinergics. Sydenham chorea is one of the common ones observed in developing countries and in some pockets in the developed as a part of rheumatic fever following a group A Streptococcal infection, primarily in the form of sore throat. Chorea usually appears after 4–6 weeks of acute streptococcal sore throat. Chorea may be the only manifestation of rheumatic fever as arthritis, carditis, and other major features may not be present any more by the time chorea appears. Presence of Sydenham chorea alone is an indication of putting the child on rheumatic fever prophylaxis; one does not need to wait for fulfillment of modified Jones diagnostic criteria. The chorea is accompanied by personality changes with anxiety, fidgetiness, and emotional liability. The symptomatic management of chorea in Sydenham chorea, if at all needed, is best achieved by the use of carbamazepine, haloperidol, valproate, or phenobarbital. The prognosis of chorea is excellent with near total disappearance over weeks to months. However, rheumatic fever prophylaxis with penicillin or other antibiotic (when penicillin sensitive) is mandatory as per standard recommendation.

Tremor

Tremor is characterized by regular rhythmic oscillatory movement of various body parts due to alternate agonist and antagonistic muscle contraction. The amplitude and speed of movement around the axis is the same in both directions of the movement. Behavior of tremor during physiological activity is important to find the etiology of the tremor. The distribution of tremor is also important. Rest tremor is best described as tremor at *repose*, typically starts when the affected body region is at rest, and goes away or at least gets significantly better on use of the limb. Typical example of the rest tremor is the one commonly observed in Parkinson disease or Parkinsonism. Usually, this type of tremor is slower, coarser, and it may occur in a pill rolling pattern. Tremor brought on with activity is called as action tremor. This tremor usually is faster, gets exaggerated on anxiety, does not change in frequency and amplitude in specific posture, or during specific targeted activity. This type of tremor is also called as exaggerated physiological tremor, rarely this produces significant dysfunction. However, recognition of this type of tremor may give a significant clue to some underlying serious but potentially treatable clinical conditions as mentioned in **Table 4**. The tremor which appears only before reaching a target, for example while doing finger nose

or heel to shin testing, is called intention tremor, alternatively termed as terminal tremor. Intention tremor is a cardinal feature of cerebellar dysfunction. This type of tremor is usually accompanied by ocular nystagmus, cerebellar dysarthria, and ataxia. Postural tremors are characterized by tremors in specific posture or during specific action. Essential tremor is a disorder, primarily characterized by tremor, which gets exacerbated in certain posture, such as outstretched arm, followed by hyperpronation of the forearm; bringing the fingers in front of the chest about to touch each other keeping the arms abducted at 90°, lifting arms above head and then full pronation or supination. The tremor of essential tremor also gets more prominent on useful activities such as holding a glass of water, pouring water from one glass to the other, using spoon, holding a piece of paper, handwriting, drawing a spiral, or line **(Fig. 2)**. Thus the tremor of essential tremor can also be considered as postural kinetic tremor. The other rare type of postural tremor seen primarily in adult is the orthostatic tremor, which starts abruptly when the affected person attains an upright posture, and the tremor involves lower body predominantly; this goes away when the person takes a few steps. This is one rare example of improvement of an involuntary movement on activity; most others get worse with activity.

Infantile Tremor Syndrome affects children between 5 months and 30 months of age, characterized by developmental regression, tremor, pallor, skin pigmentation, and discolored hair. This type of
I enjoy playing soccer, my position in goalie.

Figure 2 Archimedes spiral drawing (inner line by patient) with either hand; line drawing, handwriting sample obtained from a 10-year-old boy with essential tremor

tremor, initially described only from Indian subcontinent, is now described from countries such as Iraq, Afghanistan, Myanmar, Somalia, Nigeria, and Turkey. The etiology is inconclusive, and most likely multifactorial. Theories are: a) *related to nutrition:* nutritional recovery from malnutrition to specific nutritional deficiency of vitamin B$_{12}$, magnesium, zinc; b) Infection-encephalitis; c) Metabolic deficiency of tyrosine metabolism, d) Toxic—still unidentified toxin from mother's breast milk. Tremor is noted in more than 95% cases affected; tremor starts abruptly in the upper limbs, later becomes generalized; intermittent to start with, later continuous; cry becomes tremulous. The tremor is usually coarse, 6–12 Hz, mostly action, and may have some rest tremor. Pretremor phase of the infantile tremor syndrome lasts for 2–12 weeks, tremor phase for an average of 6 weeks. On appropriate nutritional intervention, there is recovery in about 1–6 months. Rare mortality occurred due to intercurrent infections. Small studies have shown some persistence of subnormal cognitive abilities even after recovery from the illness. **Table 4** shows different types of tremor based on clinical characteristics and their causes.

Tics

These are brief, stereotyped semi-voluntary movements/jerks/posture/activity of various body parts, or production of a sound, associated usually with an urge, at least partially voluntarily suppressible, typically producing anxiety, if forced to suppress for a long time. Usually, the child can control them reasonably well at school or during the game, to be apparently released with more frequency or severity after coming back from school or after the game is over. Anxiety or stress may bring it on or make it worse. The course, typically, is fluctuating in childhood with periods (days to weeks) of worsening interrupted by periods (days to weeks) of improvement. There are two broad types of tics—motor, characterized by motor phenomenon, which may again be simple or complex. *Simple motor tic* is characterized by simple brief motor activity, whereas more complex movements are classified as *complex motor tic*, more so if, it mimics a physiological motor activity. The typical examples of simple motor tics are eye blinking, squinting, forceful eye gaze, opening of mouth, lip-smacking, head nodding, shoulder shrugging, facial grimacing, finger tapping, body jerking, stiffening of limbs. Examples of complex motor tics include combination of more than one of the above occurring concurrently, compulsive touching of the corners, touching of genitalia, obscene gestures, compulsive touching of others, skipping or jumping while walking, odd body postures while standing or walking.

The tic characterized by production of a *sound* is called vocal tic, which can be either *simple* or *complex* based on the simplicity of the sound. Vocal tics may be simple such as sniffing, throat clearing, grunting, tongue clicking, sighing, chirping, barking, or cough. Examples of complex tics are burping, hiccup, involuntary utterances of obscenities or swearing (coprolalia), repetitive utterances of words (echolalia, repeating other person's words and palilalia, repeating later portions of his own words).

Tic disorders are classified as *transient* tic disorder, if the tic symptoms resolve completely in 1 year; *chronic*, if lasts more than 12 months. Tourette syndrome is diagnosed, if multiple motor and at least one vocal tic persist continuously or intermittently for more than a year. Though Tourette syndrome is defined based on the presence of tics, the major management problem may stem from the comorbidity with this disorder, namely, attention deficit hyperactivity disorder (50%), obsessive compulsive symptoms (30%), obsessive compulsive disorders (30%), anxiety (5–10%), headache (up to 3/4th), sleep problem (60%), depression (5%). There is no unifying treatment for Tourette syndrome, and all the comorbidities are to be managed separately.

Stereotypy

Abnormal involuntary repetitive, stereotyped, patterned movements or vocalization, without changing patterns with time (tics change with time), usually time locked with excitement or boredom, may not be associated with any urge or compulsions. Unlike tics, the stereotypies last longer, as long as the inciting factor such as excitement continues. However, these movements stop, if attention is diverted. Usually, this starts before 2 years of age, much earlier than tics, which starts at about 6 years of age. As in tics, stereotypies are also classified as motor and vocal, and each as simple and complex. Some common examples of motor stereotypies are clapping, jumping, finger ringing, finger taping, piano playing movement with fingers, severe body or head rocking, twisting of limbs mimicking dystonia, complex body twisting and rhythmic body jerking or pelvic jerking. Examples of vocal stereotypies are hyperventilation, grunting or cooing sounds, mimicry, repeating the movie acts or dialogues. Stereotypies usually happen in the context of an underlying autistic spectrum disorder, communication problem, or a cognitively challenged state. These stereotypies are classified as secondary. About 5% of all stereotypies, however, happen in an apparently normally developing child with normal intellect and social skill. These stereotypies are classified as *primary*. Secondary stereotypies are more prolonged than primary, have more vocal and complex forms. Stereotype by itself is usually benign but its importance lies in the substrate in which this happens, for example, autistic spectrum disorders, or mental retardation, or communication problem.

DISORDERS WITH ABNORMAL INVOLUNTARY MOVEMENTS

Detail description of all the movement disorders in children is not possible in a single chapter. More emphasis is given on the disorders specific to the developing countries. Disorders with abnormal involuntary movements in pediatric age group can be broadly classified into four categories, which are:
1. *Development related:* The presence of motor phenomena that are considered normal during the developing period of life, self-limiting, improve or totally disappear on maturity.

Table 4 Different types of tremors in children

Variety	Causes
Rest tremor	Juvenile Parkinson disease, Wilson disease, drugs/toxins-like neuroleptics, manganese
Postural tremor	Essential tremor, Orthostatic tremor
Intention tremor	Cerebellar disorders, alcohol
Action tremor	Exaggerated physiological tremor—anxiety, hyperthyroidism, pheochromocytoma, hypoglycemia, drugs/toxins, e.g., stimulants, bronchodilators, valproate, lithium, mercury, arsenic, cyanide, cyclosporine, nicotine, selective serotonin reuptake inhibitors
Special types of tremor	Spasmus nutans, shuddering spells, jitteriness, Bobble-headed Doll syndrome, Infantile tremor syndrome, psychogenic tremor

2. Paroxysmal movement disorders.
3. Extrapyramidal disorders with primary (genetic/idiopathic) and secondary (hereditary/metabolic/other) known etiology (such as Wilson disease).
4. *Static encephalopathy*—producing chronic motor dysfunction (such as postkernicterus dystonia, mixed form of cerebral palsy).

Development-related Movement Disorders

Some abnormal movements are noticed during the stages of early development, but disappear later with maturation of the neuraxis. It is extremely important for a pediatrician to be familiar with these conditions as their prompt diagnosis will not only help lower the cost of unnecessary investigations, but also will allay the anxiety among the parents. Some examples include physiological infantile dystonia, physiological chorea of infancy, and benign neonatal and infantile myoclonus.

Extrapyramidal Disorders

Abnormal involuntary movements are quite common manifestations of neurometabolic/degenerative disorders. The details of the description of the extensive list of the diagnoses in this subgroup are out of the scope of this chapter due to the limitation of space. These are covered in the chapter on neurodegenerative disorders. A few important treatable conditions are discussed so as not to miss those diagnoses.

Wilson Disease

This diagnosis has to be considered in any child presenting with any acquired movement disorders. This is an autosomal recessive disorder secondary to mutation in the *ATP7B* gene encoding for copper transporting ATPase 2 protein responsible for transport of copper from liver to other parts of the body. Blood test for serum ceruloplasmin, copper level and eye examination for Kayser-Fleischer (KF) ring will confirm the diagnosis and is a must in every case of acquired movement disorders with onset after 3 years of age. Any type of involuntary movements such as dystonia, chorea, myoclonus, Parkinsonian features (bradykinesia, rigidity, tremor), cerebellar ataxia, cognitive/behavioral symptoms are the principal neurological target symptoms. Neurological involvement occurs typically after the earlier hepatic involvement. Copper chelation therapy using d-penicillamine or trientine is very useful, more so in combination with Zinc which prevents GI absorption of copper. The neurodeficit is largely reversible, if diagnosed and treated early. Liver transplantation is also promising as the last treatment option.

Myoclonus Dystonia

A combination of essential myoclonus and dystonia in an otherwise neurologically normal child with a normal MRI brain is very suggestive of this diagnosis. Epsilon-sarcoglycan (SGCE) mutation is the underlying genetic defect, but only about 50–70% cases may have this mutation. In suspected cases, a trial of trihexyphenidyl and/or clonazepam is very helpful. In selected cases, unresponsive to medication, deep brain stimulation of the bilateral globus pallidus pars interna is very effective.

Dopa Responsive Dystonia and Juvenile Parkinson Disease

Typically, the child with Dopa responsive dystonia has the following characteristics: 1) starts with dystonia affecting the legs asymmetrically; 2) diurnal variation with worsening during evening; 3) fatigability and improvement on rest or sleep; 4) normal cognition; 5) normal MRI brain. In such a case, it is

mandatory to try a levodopa-carbidopa combination. In a typical case of autosomal dominant type of Dopa responsive dystonia (Segawa disease), caused by a mutation of the *GCH1* gene coding for the enzyme, guanosine triphosphate (GTP) cyclohydrolase in the pterin pathway, the response to small dose of levodopa is dramatic and sustained without producing any side effect even when used over decades. If the diagnosis of Dopa responsive dystonia is suspected at whatever age, it is recommended to try levodopa so as not to miss this eminently treatable condition. A trial of levodopa should be instituted in any child with generalized dystonia as the first medication. Other medications for dystonia are tried only after adequate trial with levodopa-carbidopa has been completed. Juvenile Parkinson disease may complicate the course of Dopa responsive dystonia, if untreated. The typical features of Parkinson disease in the form of bradykinesia, rigidity, rest tremor are present in this condition. When this condition occurs due to genetic defects other than the one associated with Dopa responsive dystonia, the treatment response may not be that encouraging and there may be a lot of dyskinesia or dystonia complicating the clinical scenario.

Investigations in Pediatric Movement Disorders

The following are the common investigations undertaken for evaluation of movement disorder in children: magnetic resonance imaging (MRI) of the brain, biochemical analysis of blood/urine/CSF, neurophysiology, and genetic study, in selected cases.

TREATMENT OF PEDIATRIC MOVEMENT DISORDER

Dopa Responsive Dystonia and Juvenile Parkinson Disease

Levodopa-carbidopa (4:1): 1–5 mg/kg/day (calculated on levodopa content), to be taken without protein food; 100% response, no side effect, if the diagnosis of Dopa responsive dystonia is correct.

Other Dystonias

The medical treatment response is not much encouraging. Following medications are often tried on a trial and error basis:

- *Anticholinergics:* Trihexyphenidyl, benztropine useful in about two-thirds of cases; limiting side effects are cognitive/behavioral and constipation.
- Benzodiazepines including baclofen, clonazepam useful in about 60% cases.
- Dopamine receptor blockers may help in up to 50% cases; may have dyskinetic side effects.
- *Tetrabenazine:* Dual action with dopamine depletion and receptor blocking with less dyskinetic side effects, may help in recalcitrant cases.
- *Drug-induced dystonia:* Anticholinergics such as benadryl, trihexyphenidyl, benztropine; the response is excellent with any of them.

Tardive Dyskinesia

Uncommon in children; in case this happens, stop or lower the dose of the offending medication; anticholinergics and tetrabenazine are tried with some success.

Tremors

Essential tremor Propranolol, primidone, topiramate useful in about two-thirds cases for each.

Rest tremor Responds well to levodopa-carbidopa or Dopa agonists such as ropinirole, pramipexole.

Myoclonus

Antiepileptics such as valproate, zonisamide, levetiracetam, clonazepam; most effective for epileptic myoclonus.

- *Piracetam or 5-hydroxytryptophan:* Hypoxic myoclonus.
- Tetrabenazine tried with variable success in other cases.

Tics

Clonidine or guanfacine for tics of modest severity, also helps comorbid hyperactivity; typical antipsychotic such as haloperidol, pimozide for more severe cases; atypical antipsychotics such as risperidone, aripiprazole, olanzapine, quetiapine. Tetrabenazine is also tried with some success.

Chorea/Athetosis/Ballismus

Dopamine antagonists including pimozide, haloperidol, tetrabenazine; anticonvulsants: carbamazepine, valproate, carbamazepine, phenobarbital. Avoid use of anticholinergics as they worsen chorea or athetosis.

Myoclonus dystonia Trihexyphenidyl and clonazepam are very useful.

Hyperekplexia Clonazepam is helpful.

Surgical Management

Deep Brain Stimulation

Bilateral globus pallidum pars interna (GPi) very effective in primary dystonia in children with more than 90% persistent symptom relief. The response in secondary cases is not that encouraging, only about 33% response rate in that subgroup. Myoclonus dystonia also responds to deep brain stimulation (DBS). Some cases of severe form of Tourette syndrome also benefit from this surgical management.

Thalamic ventral intermediate nucleus Excellent response in essential tremor, though rarely needed in childhood; helpful in some other pharmacoresistant tremors of any type.

Subthalamic nucleus in severe cases of juvenile Parkinson disease, posterior subthalamic area in essential tremor.

Extirpative Surgery

Pallidotomy or thalamotomy—effective, but as these are irreversible procedures, they are currently being replaced by deep brain stimulation in the developed countries. These procedures still have a role in resource-poor developing countries.

IN A NUTSHELL

1. Movement disorders are divided into two basic categories: *hypokinetic* and *hyperkinetic*.
2. Hyperkinetic disorders manifest with either single or varying combination of "abnormal involuntary movements" such as dystonia, chorea, athetosis, ballism, tics, myoclonus, tremor, and stereotypy.
3. Hypokinetic disorders are uncommon in childhood. A few childhood movement disorders which may have Parkinsonian features include early onset Parkinson's disease, Wilson disease, Juvenile Huntington disease, and Hallervorden-Spatz disease.
4. Disorders with abnormal involuntary movements are classified into four categories: development related; paroxysmal movement disorders; extrapyramidal disorders; and static encephalopathy.
5. MRI of the brain, biochemical analysis of blood/urine/CSF, neurophysiology, and genetic studies are the common investigations undertaken for evaluation of movement disorders.
6. Both medical and surgical treatments are available.

Chapter 42.24
Childhood Ataxia
Asuri N Prasad

Ataxia is defined as an inability to maintain normal posture and smoothness of movement. Additional neurological problems such as seizures and movement disorders (e.g., dystonia, chorea) may accompany ataxia. Consequently, many variations are encountered in the clinical phenotype, ranging from findings of pure cerebellar dysfunction to mixed patterns of involvement reflecting extrapyramidal pathways, brainstem, and cerebral cortical involvement. To consider the entire gamut of diseases that can lead to ataxia as a symptom in children would be beyond the scope of this chapter. However, the reader will be able to develop a clinical approach based on the information provided in this discussion and select suitable laboratory tests that would help confirm a diagnosis. Clearly, treatment options may have to be individualized, and as outcomes are dependent on the nature of the underlying condition and its natural history.

CEREBELLAR FUNCTION

Principal cerebellar functions involve control and modulation of locomotion, postural control, voluntary movements, and rarely cognition. Lesions of the midline cerebellar vermis produce truncal and gait ataxia, while involvement of the lateral cerebellar hemispheres produces a picture dominated by limb ataxia. Interruption of afferent and efferent connections within the neocerebellar system results in an ataxic gait (i.e., swaying in the standing posture, staggering while walking, with a tendency to fall and the adoption of a compensatory wide base), scanning dysarthria, explosive speech, hypotonia, intention tremor (i.e., oscillation of limbs that is pronounced at the end of a planned movement), dysdiadochokinesia (i.e., impaired alternating movements), dysmetria (i.e., impaired judgment of distance), decomposition of movement, and abnormalities of eye movements (i.e., nystagmus).

EPIDEMIOLOGY

The prevalence of childhood ataxia varies by region, and by etiology. A prevalence rate of almost 26/100,000 children in Europe was reported in a recent systematic meta-analysis of published data on childhood ataxia. The causes of ataxia vary depending on the methodology adopted. A study looking at pediatric chronic ataxia relied on a database search at a tertiary care referral center in Canada came up with annual crude incidence rate of 3.1 per 100,000 and a crude period prevalence rate of 6.62 per 100,000. Overall, it is likely that the prevalence and incidence of ataxia is significantly underestimated.

ETIOLOGY

Box 1 lists the causes of acute ataxia in children. The etiologies are varied, involving; parainfectious, toxic-metabolic, vascular/ischemia, immune-mediated inflammation, trauma, tumors, paraneoplastic conditions. As such postinfectious, immune-mediated inflammatory conditions, as well as posterior fossa tumors are important considerations and are encountered quite frequently.

Chronic pediatric ataxias have structural, genetic and metabolic causes. A classification system has been developed on the basis of presentation and progression, involvement of multiple systems, and more specific symptoms such as epilepsy. Under each broad category, the mode of genetic inheritance is used as a basis to further categorize conditions and include traditional as well as nontraditional modes of inheritance (maternal inheritance, triplet repeat disorders, imprinting disorders, etc.) **(Box 2)**.

ACUTE ATAXIA

The presentation is usually striking and represents an acute change from a normal neurological baseline. The features are of a cerebellar syndrome with ataxic gait being a primary feature in midline lesions, and in toxic metabolic etiologies. Asymmetry and lateralization of abnormalities in terms of coordination, limb ataxia, and lurching to one side may be seen with unilateral lesions

---

BOX 1 Causes of acute ataxia in childhood

- *Postinfectious:* Varicella, Epstein-Barr, enterovirus
- Toxic-drug induced
- Tumor-posterior fossa
- Hydrocephalus
- Acute demyelinating encephalomyelitis
- Basilar migraine/migraine equivalents
- Posterior circulation strokes
- Neuroblastoma-associated opsoclonus-myoclonus-ataxia
- Benign paroxysmal vertigo
- Guillain-Barré syndrome and the Miller-Fisher Variant

BOX 2 Classification of ataxia using a genetic-biochemical basis

Nonprogressive ataxias:
- Pure congenital cerebellar ataxias with or without cerebellar hypoplasia
  - Autosomal recessive
  - Autosomal dominant
  - X-linked
  - Unknown
- With posterior fossa malformations—autosomal recessive (e.g., Dandy-Walker syndrome)
- *Congenital ataxia syndromes with cerebellar malformations:*
  - Autosomal recessive (e.g., Joubert syndrome)
  - X-linked recessive (e.g., X-linked congenital cerebellar hypoplasia and external ophthalmoplegia)

Intermittent/episodic ataxias:
- Autosomal dominant—channelopathies [e.g., episodic ataxias (EA) 1, EA 2]
- Autosomal recessive—enzyme defects [e.g., maple syrup urine disease (MSUD), urea cycle defects]
- X-linked—enzyme defects [e.g., ornithine transcarbamylase (OTC) deficiency]

Progressive ataxias with or without multisystem involvement:
- Autosomal dominant—ataxias with spinocerebellar dysfunction, triplet repeat disorders [e.g., SCA 1-23, dentatorubropallidoluysian atrophy (DRPLA)]
- Autosomal recessive
  - Ataxias with spinocerebellar dysfunction, triplet repeat disorders (e.g., Friedreich ataxia)
  - Impaired DNA repair mechanisms (e.g., Ataxia telengiectasia)
  - Enzyme defects (e.g., Refsum disease)
- Maternal inheritance—Mitochondrial disorders (e.g., MERRF)

Ataxias with polymyoclonus and seizures:
- Autosomal recessive
  - Dodecamer repeat expansions (e.g., Lafora body disease)
  - Enzyme defects (e.g., neuronal ceroid lipofuscinosis)
- Maternal inheritance—Mitochondrial cytopathies [e.g., myoclonic epilepsy with ragged-red fiber disease (MERRF), mitochondrial encephalomyopathy, lactic acidosis and stroke like episodes (MELAS)]

Other:
- Angelman syndrome
- Fragile X-related ataxia/tremor

of the cerebellum and brainstem connections. There may be other features such as nystagmus, pyramidal and extrapyramidal features, and involvement of higher cerebral functions depending on etiology.

Approach to a Patient with Acute Ataxia

The process of evaluation depends on important data elements collected through history, and examination findings. Information on exposure to infections, a prodromal illness, vaccinations, trauma, medications, toxins are of vital importance. Associated symptoms of headache, signs of raised intracranial pressure may point towards the presence of an intracranial lesion such as a tumor. Examination findings may be particularly significant in picking up on signs of cerebellar dysfunction as well as involvement of extrapyramidal pathways (dystonia). Presence of hyper-reflexia and spasticity points to an upper motor neuron involvement. Associated areflexia and motor weakness suggest Guillain-Barré syndrome as likely etiology. Signs of vestibular dysfunction elicited by a Dix-Hallpike maneuver may confirm a peripheral sensory contribution to the symptoms of ataxia.

Laboratory investigations should include; drug and toxicology screen, neuroimaging studies, lumbar puncture and CSF analysis (lactate, protein, oligoclonal banding, antibody screens for viral studies) can provide specific clues to inflammatory, demyelination, and the presence of intracranial pathology. Nerve conduction and electromyography may show a conduction block, loss of F and H waves consistent with peripheral demyelination. Metabolic screening should be included as a part of initial work-up by including blood lactate, ammonia, blood and urine amino acids, urine organic acids analysis, if available (aminoacidopathies, urea cycle defects, and mitochondrial disorders). Other assays may include carnitine levels, plasma acylcarnitine profile may be helpful to identify fatty acid oxidation disorders. Specialized scans (MIBG), other body scans may be considered when paraneoplastic disorders are in the differential. The approach is summarized in **Figure 1**.

INTERMITTENT/EPISODIC ATAXIA

Episodic Ataxia 1

Episodic ataxia 1 (EA1) is a rare autosomal-dominant disorder and represents a channelopathy. It is caused by point missense mutations that affect the human voltage-gated potassium channel (*KCNA1* gene on band 12p13). Affected individuals report continuous myokymia between attacks of ataxia that last for seconds to minutes. Ataxia of an episodic nature may also be accompanied by focal epileptic seizures (some individuals in affected families). Symptoms are precipitated by movement, startle, or emotion. Electroencephalography (EEG) may show continuous rhythmic muscle discharge artifact, which may become more prominent with hyperventilation. Electromyography is the only helpful investigation; it usually demonstrates continuous motor unit activity in all patients. Partial responses to acetazolamide, carbamazepine, phenytoin, and phenobarbital have been reported.

Episodic Ataxia 2

Episodic ataxia 2 (EA2) is an autosomal-dominant disorder that has been associated with mutations that affect the calcium channel (*CACNA1A*) gene at the 19p13 locus. It is allelic to familial hemiplegic migraine and spinocerebellar ataxia type 6 (SCA6), wherein mutations affecting the same gene have been described. Intermittent midline cerebellar dysfunction characterized by bouts of ataxia, nystagmus, dysarthria, and vertigo occurs. Headache can be a feature in some families and the absence of myokymia is notable. Attacks are triggered by stress, exercise, and fatigue, among others. The diagnosis is confirmed by *CACNA1A* gene mutation testing. A few patients with EA2 may respond to acetazolamide.

CHRONIC ATAXIA

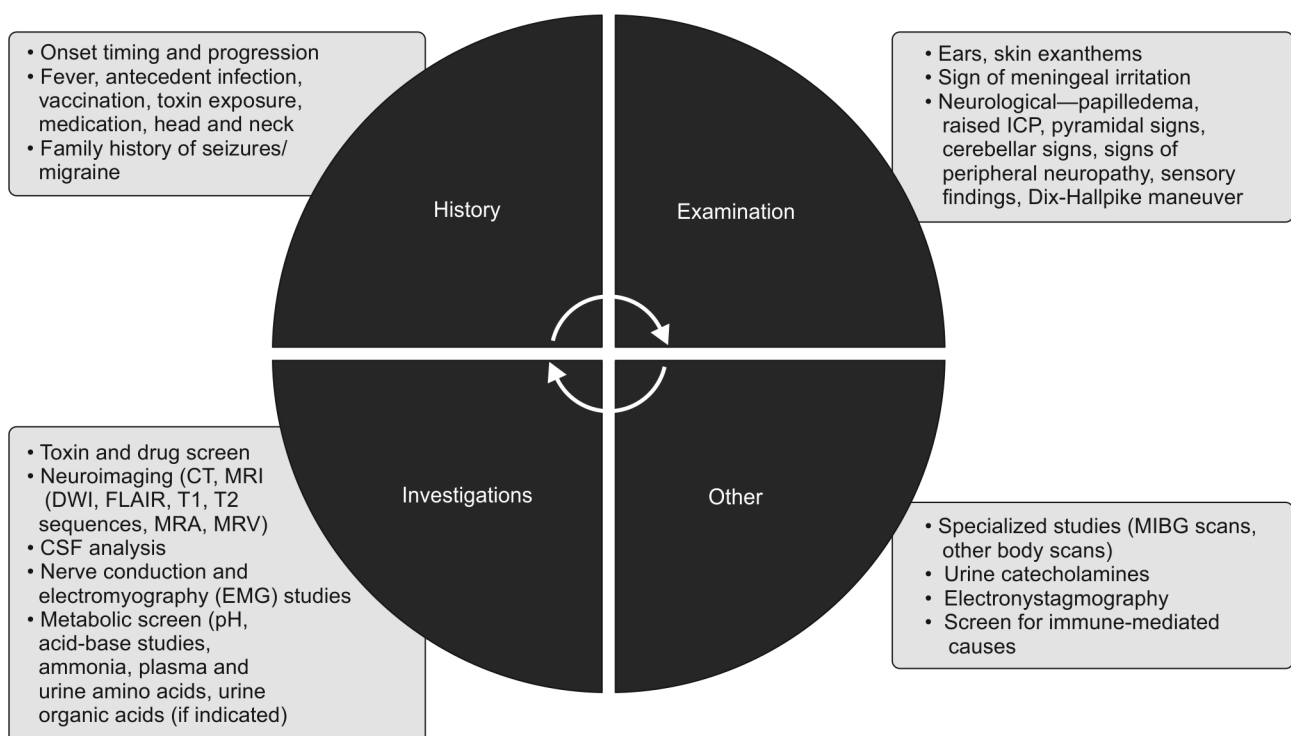
The discussion below addresses selected conditions that are associated with chronic ataxia within the framework of the classification schema adopted in this chapter.


Figure 1 Investigations for acute childhood ataxia

Nonprogressive Cerebellar Ataxias (NPCA)

Early features in the first few years of life include; hypotonia, developmental delay, feeding difficulties and oromotor apraxia, speech delay secondary to articulatory difficulties, ataxia and cognitive difficulties may be recognized at a later age. Genetic assessments of the family may disclose a specific pattern of inheritance.

Laboratory findings Genetic mutation tests available only in selected conditions, for example, for Joubert syndrome. Metabolic screening is usually negative. MRI is superior as it permits better visualization of the posterior fossa. Variable degrees of hypoplasia of cerebellar vermis are usually reported. In severe cases, the entire vermis may be absent, and associated abnormalities in cerebellar hemispheres noted. In mild cases, however, the cerebellum is morphologically normal on imaging studies. Associated abnormalities of the brainstem and supratentorial structures may be of additional value in the diagnosis of syndromes such as Dandy-Walker malformation.

Joubert Syndrome

Currently, a group of conditions termed Joubert syndrome and related disorders (JSRDs), share the neuroimaging finding of *molar-tooth* sign as a common feature. The neurological presentation of JS includes hypotonia evolving into ataxia, developmental delay, abnormal eye movements, and neonatal breathing abnormalities. Multiorgan involvement, mainly of the retina, kidneys, and liver, is of a variable nature. To date, 16 causative genes have been identified, encoding for proteins expressed in the primary cilium or its apparatus leading to the description of a growing field of disorders due to mutations in ciliary proteins that are collectively known as *ciliopathies*. These include isolated nephronophthisis, Senior-Loken syndrome, Bardet-Biedl syndrome and, in particular, Meckel syndrome, which is allelic at JSRD at seven distinct loci. Significant genotype-phenotype correlates are emerging between specific clinical presentations and mutations in JSRD genes, with relevant implications in terms of molecular diagnosis and clinical follow-up.

PROGRESSIVE RECESSIVELY INHERITED ATAXIAS

Friedreich Ataxia

Friedreich ataxia was the first identified recessively inherited condition with a mutation involving a triplet repeat expansion. Ninety-six percent of patients are homozygous for a GAA expansion in intron 1 of the *X25* gene. The number of GAA repeats ranges from 7 to 38 in normal alleles and from 66 to greater than 1700 triplets in disease-causing alleles. The remaining cases are compound heterozygotes for a GAA expansion and a frataxin point mutation. The mutation leads to formation of the abnormal protein termed *frataxin*. The cells and tissues carrying this mutation appear to be sensitive to oxidative stress.

Clinical Features

A variable age of onset is noted, the key neurological features include; cerebellar ataxia, dysarthria, nystagmus, uncoordinated limb movements, hypoactive knee and ankle deep tendon reflexes, Babinski sign, impaired position sense, and impaired vibratory sense. Systemic involvement includes cardiac and skeletal features; symmetric, concentric, hypertrophic cardiomyopathy associated subaortic stenosis, eventually leading to congestive heart failure, while the skeletal features include; pes cavus, scoliosis, and hammer toes. An abnormal glucose tolerance test, diabetes mellitus, and diabetic ketoacidosis are late manifestations.

Laboratory Findings

An electrocardiogram, and echocardiogram are part of the cardiac assessment. Nerve conduction and EMG will confirm the involvement peripheral nerves. Imaging studies of the nervous system disclose cerebellar atrophy and a thin spinal cord. Research studies confirm impaired oxidative evidence of iron accumulation within mitochondria of FRDA fibroblasts subjected to oxidative stress, resulting in impaired respiratory function. Molecular genetic testing is available.

Treatment

No specific treatment other than symptomatic and supportive care is available. Treatment protocols currently involve the use of Coenzyme Q and other antioxidants that are being newly developed (mitoquinone, idebenone). Preliminary trials suggest clinical improvements based on the bioenergetics of cardiac and skeletal muscle, and slowing of progression.

Ataxia with Selective Vitamin E Deficiency

This is a rare autosomal-recessive disorder resulting from a mutation that affects the gene for alpha-tocopherol transfer protein. It is phenotypically similar to Friedreich ataxia, with head titubation (28%), spinocerebellar ataxia, areflexia, and proprioception loss. Skin is affected by xanthelasmata and tendon xanthomas. Age of onset varies between 2 years and 52 years and usually occurs when younger than 20 years and slowly progresses over decades. Low-to-absent serum vitamin E and high serum cholesterol, triglyceride and beta-lipoprotein are characteristic of this disorder. Treatment consists of vitamin E supplementation. A dose of 400–1200 IU/day improves neurologic function. This should be maintained for life.

Coenzyme Q (10) (CoQ)/Ubiquinone Deficiency

This is an autosomal recessive disorder presenting with five phenotypes: a myopathic form, a severe infantile neurological syndrome associated with nephritic syndrome, an ataxic variant, Leigh syndrome and a pure myopathic form. CoQ (10) or ubiquinone plays a key role in oxidative phosphorylation (OXPHOS) in that it distributes electrons between the various dehydrogenases and the cytochrome segments of the respiratory chain. Cerebellar ataxia is the most common phenotype. Muscle CoQ deficiency associated with cerebellar ataxia and cerebellar atrophy as the main neurological signs. Biochemically, the hallmark of CoQ deficiency syndrome is a decreased CoQ concentration in muscle and/or fibroblasts. Patients with primary CoQ deficiency may benefit from CoQ supplementation, although the clinical response varies even among patients with similar phenotypes.

Abetalipoproteinemia

This rare autosomal-recessive disorder is characterized by low levels of low-density lipoproteins (LDLs) and very low-density lipoproteins (VLDLs) in the blood. The biochemical basis is attributable to defective assembly and secretion of apolipoprotein B (Apo-B)–containing lipoproteins by the intestines and the liver as mutations appear to affect the microsomal triglyceride transfer protein (*MTP*) gene.

Clinical Features

The early features are of abnormalities of tone, areflexia, proprioceptive dysfunction, loss of reflexes, and Babinski sign (prominent findings). By 5–10 years, gait disturbances and cerebellar signs appear. Associated gastrointestinal manifestations in the early years include; a malabsorptive steatorrhea and abdominal distension. Pes cavus and scoliosis present in some patients, while pigmentary retinopathy leads to visual symptoms at a late stage.

Laboratory Findings

Acanthocytosis on peripheral blood smears is a constant finding, the lipid profile shows decreased levels of serum cholesterol, elevated high-density lipoprotein cholesterol, low LDL and VLDL and triglyceride levels. Molecular genetic testing is available.

Treatment

High-dose supplementation of vitamin E has a beneficial effect on neurologic symptoms and other fat-soluble vitamins (D, A, K) must be supplemented to correct secondary deficiency related to the malabsorptive state.

Hypobetalipoproteinemia

The condition is clinically indistinguishable from abetalipo-proteinemia especially in its homozygous form, but the inheritance is autosomal dominant. It is caused by mutations that affect the *Apo-B* gene, which affects turnover of apolipoprotein B. Laboratory findings are characterized by extremely low plasma levels of apolipoprotein B, as well as low levels of total- and low-density lipoprotein (LDL) cholesterol values.

Ataxia Telangiectasia

This progressive, recessively inherited ataxia presents in early childhood. A defective truncated protein that belongs to the (possibly phosphatidylinositol-3 kinase family of proteins) results from mutations that affect the *ATM* gene locus. The function of this protein is to phosphorylate key substrates that are involved in DNA repair. The disease begins when patients are aged 1–3 years.

Clinical Features

Extrapyramidal features include; gait abnormalities, choreo-athetosis, dystonia, and oculomotor apraxia in the early stages. Progressive ataxia and slurred speech and features of a cerebellar syndrome also become evident. Immunodeficiency and increased susceptibility to infections is common, cutaneous and bulbar telangiectasia (present in teenagers and older individuals) appear later and are of clinical diagnostic value. Due to abnormal chromosomal fragility and DNA repair defects, there is an increased susceptibility to cancer (e.g., leukemia, lymphoma).

Laboratory Findings

Molecular genetic testing is performed for mutations affecting the *ATM* gene locus (11q22.3). For those patients in whom mutations cannot be identified, other supportive laboratory evidence must be sought. Elevated (>10 ng/mL) serum alpha-fetoprotein in 90–95% of patients is often supportive evidence in the face of clinical features and can be a useful marker. Abnormalities in colony survival assay (colony formation of a lymphoblastoid cell line following irradiation) as well as karyotyping abnormalities involving 7–14 chromosomal translocation in 5–15% of cells after phytohemagglutinin stimulation of lymphocytes in peripheral blood may demonstrate breakpoints involved in translocation at the 14q11 and 14q32 sites.

Ataxia Telengiectasia Like Disorders

This group includes the following disorders; ataxia with oculomotor apraxia type 1 (AOA1), ataxia with oculomotor apraxia type 2 (AOA2) and ARSACS.

Ataxia with Oculomotor Apraxia Type I (AOA1)

The disorder begins in childhood with an onset between 2 years and 10 years proceeding to loss of ambulation in 7–10 years. The gene (*APTX*) locus at 9p13.3 codes for a protein aprataxin which appears to have a role in DNA repair. Initially, the disorder presents as a cerebellar ataxia, followed in a few years by oculomotor apraxia

progressing to complete ophthalmoplegia are key features. Chorea and upper limb dystonia are common. While normal cognition is reported in Portuguese families, decline in cognition is noted in Japanese kindred. Areflexia associated with motor neuropathy is an added feature in more than 90% cases. Neuroimaging shows marked cerebellar atrophy in affected individuals, and the EMG will demonstrate signs of axonal neuropathy.

Ataxia with Oculomotor Apraxia Type 2 (AOA2)

The disorder begins in the second decade (3–30 years) with slow progression. Mutations are described in the *SETX* gene, located at 9q34 and the gene product is called *senetaxin*, the protein is thought to function as a helicase involved in RNA maturation and termination. Similar to *AOA1*, progressive cerebellar ataxia and oculomotor apraxia are key features. Areflexia associated with an axonal sensorimotor neuropathy leads to loss of ambulation. Pyramidal signs and dystonia are added features. Affected patients uniformly demonstrate cerebellar atrophy on MR imaging while elevated alphafetoprotein (> 20 ng/mL) but generally lower than seen in ataxia-telengiectasia. Elevated serum cholesterol is seen in almost 50% of affected individuals. Supportive and rehabilitative measures are the only options currently available.

Infantile-onset Spinocerebellar Ataxia

Infantile-onset spinocerebellar ataxia (IOSCA) is an autosomal recessive neurodegenerative condition characterized by signs of developmental regression usually after the first year, followed by appearance of ataxia, generalized hypotonia, loss of deep-tendon reflexes, and athetosis. By the age of seven years, ophthalmoplegia and sensorineural deafness are evident. In later years, there is loss of ambulatory capacity; sensory axonal neuropathy, optic atrophy, autonomic nervous system dysfunction, and hypergonadotrophic hypogonadism in females become evident. Myoclonic jerks or focal clonic seizures that progress to epilepsia partialis continua followed by status epilepticus and an epileptic encephalopathy represent a catastrophic phenotype. Mutations in *C10orf2* gene form the basis of this disorder, which leads to a form of mitochondrial DNA depletion particularly in the nervous system. Both homozygous and compound heterozygous mutations are described.

Management

All routine screening and metabolic tests are normal, muscle pathology is normal, the liver may show mitochondrial DNA depletion. Targeted mutational analysis is available. No definitive treatment is available. Valproic acid should be avoided in treatment of epilepsy.

PROGRESSIVE DOMINANTLY INHERITED ATAXIAS

Spinocerebellar Ataxias

The number of dominantly inherited spinocerebellar ataxias (SCA) that have been described has increased to 26 and are labeled SCA1 onwards in sequence. The genetic basis for most of these disorders is related to expansion of triplet nucleotide repeats. A great degree of overlap in phenotype is noted including the age of onset, with the major group of symptoms related to cerebellar and spinocerebellar pathway dysfunction. Neuroimaging studies are relatively non-specific findings. These mostly affect adults, rarely children may be affected. The majority of the SCA are accounted for by SCA1, SCA2, SCA3, SCA6, SCA7, and SCA8 subtypes, the remaining types are quite rare and have been reported in few families from both Caucasian and non-Caucasian background. SCA1, 2 and 3 have been reported in the South Indian population and account for more than a third of cases. SCA12 seems to be prevalent in the

Indian context Agarwal ethnic background. Spinocerebellar ataxia (SCA-2) and SCA-8 may rarely present in children. Clinical features of SCA2 include the following; age of onset (2–65) years. Ataxia, facial fasciculation, lid retraction, reduced ocular saccadic velocity are key features. The gene locus is 12q24.1 and the SCA 2 protein product is termed ataxin 2. The CAG repeat expansion in affected individuals is 34–400 (15–31 normal range). Spinocerebellar ataxia (SCA-8) is linked to an untranslated CTG expansion on 13q21. Clinical features include onset of symptoms ranging from age 18–65 years, with a mean of 39 years. Dysarthria and gait instability (commonly initial symptoms) examination findings include spastic dysarthria, nystagmus, limb spasticity, limb and gait ataxia, and diminished vibration perception. Progression is generally slow.

APPROACH TO A PATIENT WITH A SUSPECTED INHERITED ATAXIA

The assessment of the patient involves obtaining a detailed clinical history complemented by an appropriate neurological examination that delineates the following information:

- Age of onset
- Mode of onset (acute, subacute, chronic)
- Sex
- Natural history (nonprogressive/static, episodic, or progressive)
- Associated symptoms/signs that provide localizing information:
    – Presence of dystonia, chorea suggesting involvement of the striatum
    – Proprioceptive dysfunction suggesting involvement of spinocerebellar pathways
    – Visual deficits (retinitis pigmentosa), auditory involvement (Refsum disease)
    – Cognitive dysfunction may be encountered early and or late
    – Fluctuation of symptoms, triggers such as exercise, etc.
- Other systemic features
    – Dysmorphic features and associated congenital malformation that may suggest a specific association or clinical syndrome.
    – Cardiac (Friedreich ataxia), renal (NPCA), cutaneous (Xeroderma pigmentosa) are examples
- Family history and pedigree analysis will provide diagnostic clue and information on possible patterns of inheritance, useful for planning investigations and genetic counseling.

Once a specific clinical phenotype is delineated, the investigative process can be initiated based on the clinical features. The initial step involves obtaining an MRI. Genetic studies should include; karyotype, array CGH (deletions, duplications and chromosomal rearrangements) and specialized cytogenetic studies (Angelman syndrome), and DNA-based molecular diagnostics (spinocerebellar ataxias, recessively inherited ataxias (AOA1, AOA2, IOSCA, Ataxias associated with DNA repair defects) can be utilized to provide rapid turnaround times for diagnosis. These tests are offered through many molecular genetic laboratories around the world. Disease specific information is available at *http://www.genetests.org.*

Biochemical studies should include; acid-base studies, blood lactate and ammonia levels, Vitamin E levels, serum alpha-fetoprotein, cholesterol, lipid profiles, lipoprotein electrophoresis should be included. CSF studies should include glucose, lactate and a simultaneous blood sugar assay in addition to routine studies. Metabolic screening would involve tests such as quantitative studies for serum carnitine levels, amino acids in blood and urine, urine analysis for organic acid and acylglycines (Gas Chromatography-Mass Spectrometry (GC/MS)), plasma acylcarnitines (tandem mass spectrometry MS/MS), assays for sialotransferrins (isolectric focusing of serum transferrins) should be used selectively. Invasive tests such as nerve conduction and electromyography can be useful in exploring sensory and motor components of peripheral nerve involvement. Muscle biopsy studies include; histopathology, CoQ assays, respiratory chain studies on fresh muscle may be indicated in the context of CoQ deficiency and respiratory chain defects, mtDNA depletion (low mtDNA/nDNA ratio in tissues). An algorithmic approach is suggested **(Flow chart 1)**. Molecular diagnostic confirmation can follow targeted mutation analysis for pathogenic mutations in known genes. If molecular genetic tests are negative, third generation sequencing technologies (whole exome or whole genome sequencing) can be resorted to.

IN A NUTSHELL

1. Ataxia is defined as an inability to maintain normal posture and smoothness of movement.
2. The etiology of acute ataxia is diverse and includes parainfectious, toxic-metabolic, vascular/ischemia, immune-mediated inflammation, trauma, tumors, and paraneoplastic conditions.
3. Chronic pediatric ataxias have structural, genetic and metabolic causes.
4. Episodic ataxias are rare autosomal-dominant disorders.
5. Joubert syndrome and related disorders (JSRDs), share the neuroimaging finding of "molar-tooth" sign as a common feature.
6. Friedreich ataxia is characterized by cerebellar ataxia, dysarthria, nystagmus, uncoordinated limb movements, hypoactive knee and ankle deep tendon reflexes, Babinski sign, impaired position sense, impaired vibratory sense; and cardiac and skeletal involvement.
7. Abetalipoproteinemia is characterized by acanthocytosis decreased levels of serum cholesterol, elevated high-density lipoprotein cholesterol, low LDL and VLDL and triglyceride levels.
8. Ataxia telangiectasia results from mutations that affect the *ATM* gene locus.
9. Infantile-onset spinocerebellar ataxia (IOSCA) is an autosomal recessive neurodegenerative condition characterized by signs of developmental regression usually after the first year, followed by appearance of ataxia, generalized hypotonia, loss of deep-tendon reflexes, and athetosis.
10. Spinocerebellar ataxias are dominantly inherited and numbered as SCA1 to SCA26.

Neuroimaging studies
CT, MRI head, MRS can be helpful in identifying cerebellar atrophy, hypoplasia,
specific features such as the molar tooth sign, white matter and gray matter involvement

| Acute episodic/ intermittent ataxia | Progressive ataxia with spinocerebellar dysfunction | *Progressive ataxia* plus includes disorders that have complex neurological features +/–multisystem involvement | Ataxia plus myoclonic epilepsies |

Episodia ataxia (EA1, EA2)
• MSUD
• Hartnup disease
• Fatty acid
• Oxidation defects
• Late onset urea cycle defects

Dominant:
• Spinocerebellar ataxias (SCA)
• Recessive ataxias
• Friedreich's ataxia
• Vitamin E associated ataxia
• Abetalipoproteinemia
• Refsum's disease

Ataxia telangiectasia:
• AOA1 and AOA2
• IOSCA
• Disorders of glycosylation syndromic—Angelman's syndrome

Lafora body:
• Neuronal ceroid
• Lipofuscinosis
• MERRF
• POLG

Molecular genetic testing:
• Appropriate gene testing selection
• Metabolic screening, where indicated

Molecular genetic testing:
• SCA panel
• Friedreich's ataxia
• Metabolic tests where indicated*
• Vitamin E deficiency

Molecular genetic testing:
• Skin and muscle biopsy
• EM studies on skin
• Respiratory chain studies
• Mt DNA depletion studies

*Metabolic screening tests**
• Smears for acanthocytes, vacuolated lymphocytes
• Acid-base studies
• Blood gases
• Serum uric acid
• Plasma ammonia
• Plasma lactate
• Vitamin E levels
• Serum alfa-fetoproteins
• Phytanic acid levels
• Amino acid screening in plasma, urine and CSF
• Urine organic acid profile
• Biotinidase levels
• Liver function tests
• Plasma cholesterol, triglycerides, lipoprotein electrophoresis
• CT and MRI brain and spinal cord
• Nerve conduction EMG studies
• Evoked potentials, auditory and somatosensory EEG
* These tests are not necessary in every patient, but more targeted screening based on presentation is recommended

Specific testing:
• Chromosomal studies, array CGH
• Methylation studies, UB3E mutation analysis
• Isoelectric focusing of sialotransferrins
• Mitochondrial DNA mutation studies
• Specific enzyme assays on serum, leukocytes and cultured fibroblasts
• Trageted mutation analysis
• Depending on condition
• Whole exome sequencing*
• Whole genome sequencing*
• Whole exome and whole genome sequencing are 3rd generation sequencing platforms

* Whole exome sequencing and whole genome sequencing are 3rd generation sequencing platforms

Chapter 42.25
Neurometabolic Disorders
Mahesh Kamate

Inborn errors of metabolism (IEM) are genetically transmitted disorders that result from the lack of activity of one or more specific enzymes or defects in the transportation of proteins across cell membrane or mitochondria. As a result of this defect, there is accumulation of substances, deficiency of critical intermediary or final products and noxious excess of products of alternative metabolic pathways causing various symptoms and signs. Brain being one of the most metabolically active organs of the body, gets affected in many IEM resulting in various neurological manifestations. Hence, many of the IEMs also qualify for the term *neurometabolic disorders*. The neurometabolic disorders that have a relentlessly progressive course with irreversible loss of function are termed as *neurodegenerative disorders*.

Correct diagnosis is vital for institution of specific therapy, counseling of parents, to know the natural history of the disease, and for prenatal diagnosis. There are many misconceptions with regards to IEM like they happen only in those with a positive family history, they are difficult to diagnose and confirm, and biochemical pathways are impossible to remember. But the work-up should progress from broad widely available tests to specific ones and complex pathways are not the important part of the evaluation.

CLINICAL PRESENTATIONS

Six common neurologic presentations are described in IEM.
1. *Chronic encephalopathy:* With or without non-neural involvement
2. Acute encephalopathy
3. Stroke
4. Movement disorder
5. Myopathy with or without myoglobinuria
6. Psychiatric or behavioral abnormalities like extreme hyperactivity, agitation, psychoses, anxiety/depression.

1. Chronic Encephalopathy

Here presentation could be in the form of gray matter disease (poliodystrophy) manifesting as psychomotor retardation or dementia, seizures, impairment of special senses, and extra-pyramidal disturbances or white matter disease (leukodystrophy) presenting as motor difficulties, disorders of tone, ataxia and optic atrophy with or without peripheral neuropathy. The disorders with chronic encephalopathy can again be classified as those with and without non-neural involvement like hepatosplenomegaly, muscle involvement, skeletal involvement, skin and connective tissue involvement. The details are given in the next chapter on neurodegenerative disorders.

Psychomotor retardation/dementia is one of the most common neurological presentations of chronic encephalopathy secondary to IEM. It is usually global but the children are better in verbal skills versus motor skills. There is severe irritability, impulsivity, aggressiveness and hyperactivity. Nocturnal restlessness is very characteristic and there is progressive deterioration and associated with other features like tone abnormalities, special senses, seizures, pyramidal signs, cranial nerves, peripheral nerve involvement.

Seizures in IEM as a part of chronic encephalopathy are usually recurrent without obvious cause like hypoglycemia, have onset early in life, are associated with other neurological signs. They are usually complex partial or myoclonic seizures and are resistant to conventional antiepileptic drugs.

2. Acute Encephalopathy

The earliest signs of encephalopathy may be no more obvious than excessive drowsiness, unusual behavior, or some unsteadiness of gait. Acute or intermittent ataxia is a common sign of acute encephalopathy in older children with inborn errors of metabolism. A history of recurrent attacks of unsteadiness of gait or ataxia, especially when associated with vomiting or deterioration of consciousness, should be considered a strong indication for investigation of a possible inherited metabolic disease. It can rapidly progress to coma in a few cases in the absence of prompt treatment. Absence of focal neurological deficits and fluctuation in the clinical severity of encephalopathy are particulars pointers to IEM in a given child with acute encephalopathy. Many disorders of intermediary metabolism and disorders of energetic processes (mitochondrial and cytoplasmic) present as acute encephalopathy.

3. Stroke or Acute Onset Focal Neurological Deficits

An increasing number of inborn errors of metabolism have been reported to be associated with stroke or stroke like episodes. The important ones are listed in **Box 1**.

4. Movement Disorders

Extrapyramidal movement disorders in patients with inborn errors of metabolism are almost always associated with neurologic signs referable to other parts of the nervous system. They can be in the form of choreoathetosis, dystonia, tremors, rigidity, ataxia or myoclonus. It is typically seen in disorders such as organic acidemia and urea cycle defects. Seizures or epilepsy as a presentation is discussed in the next section in this chapter.

5. Myoglobinuria

Many of the disorders of glycolysis and fatty acid oxidation present with exercise intolerance and cramps with myoglobinuria. The disorders of glycolysis are characterized by severe muscle cramps shortly after the initiation of intense exercise. Mild, sustained exercise, such as level walking, usually is well-tolerated. Typically, if the patient rests briefly, moderate levels of activity can be resumed without discomfort. This is the so-called *second-wind* phenomenon. The painful episodes of cramps are often followed within hours by the development of wine-colored pigmentation of the urine (myoglobinuria) as a result of rhabdomyolysis. Creatine phosphokinase (CPK) levels are typically markedly elevated and rise further during exercise. Sometimes it is severe enough to cause acute renal failure. The disorders of glycolysis presenting as myoglobinuria include McArdle disease (myophosphorylase deficiency), muscle phosphofructokinase (PFK) deficiency (GSD VII), phosphoglycerate kinase deficiency, phosphoglycerate mutase and lactate dehydrogenase.

In patients with myopathy resulting from defects in fatty acid oxidation, the muscle cramps and tenderness characteristically develop after periods of exercise, when the patient is actually

at rest, and the muscle is drawing heavily on fatty acid oxidation to meet its energy requirements. There is history of episodic muscle stiffness, pain, tenderness, weakness, and myoglobinuria precipitated by prolonged exercise, exposure to cold, fasting, or intercurrent infection. Here the patients do not experience a 'second-wind' phenomenon. Between attacks, they may be completely asymptomatic, though some experience residual muscle weakness and fatigability. The CPK is elevated during attacks, but it is generally normal at other times. The fatty acid oxidation disorders presenting with myoglobulinuria include carnitine-palmitoyl transferase II deficiency, long chain acyl CoA dehydrogenase deficiency, short chain acyl CoA dehydrogenase deficiency and myoadenylate deaminase deficiency.

6. Psychiatric-behavioral Manifestations

Some neurometabolic disorders are characterized by severe behavior problems. Children with mucopolysaccharidoses have severe hyperactivity, impulsiveness, short attention span, poor tolerance of frustration, aggressiveness, and sleeplessness. Infants with hepatorenal tyrosinemia commonly exhibit acute episodes of extreme irritability. Personality changes are a common feature of Wilson disease, but usually only after the development of other neurologic manifestations of the disease. Few of the urea cycle disorders like hyperammonemia-hyperornithinemia-homocitrullinemia (HHH) syndrome have experienced periodic episodes of acute hallucinatory states lasting up to a few hours. The episodes generally occurred during periods of hyperammonemia, and the frequency of attacks decreased with improved metabolic control. Porphyria can present as chronic anxiety and depression, and marked restlessness, insomnia, depression, paranoia, and sometimes, hallucinations (during acute crises). Lesch-Nyhan syndrome presents with severe self-mutilatory behavior while presentation as acute schizophrenia has been reported with homocystinuria. Chronic forms of neurometabolic disorders like adrenoleukodystrophy can present with severe attention deficit hyperactivity and poor school performance before the onset of spasticity and visual impairment. Late onset forms of metachromatic leukodystrophy can present with social withdrawal, irritability, schizophrenia and mood disorders. Late onset GM2 gangliosidosis presents with acute psychosis, obsessional paranoia and hallucinations.

INBORN ERROR OF METABOLISM (IEM) PRESENTING AS SEIZURES AND EPILEPSY

Seizures are a common symptom in a great number of metabolic disorders, occurring mainly in infancy and childhood. In few disorders, it is the only or the predominant manifestation and hence it is important to consider neurometabolic disorder whenever we have a child presenting with seizures/epilepsy especially when it is not responding to treatment as expected. It is very important to note that few of these respond to vitamins/cofactors and have a good outcome if diagnosed earlier. Neurometabolic conditions presenting with neonatal seizures are listed in **Box 2**; and those presenting in later childhood are enumerated in **Box 3**.

Clues for IEMs as a Cause of Seizures

A positive family history of similar seizures may be seen as most of these are autosomal recessive conditions. A few of them can present as in utero hiccups and some can cause seizures in utero. Myoclonic type of seizures when present also may point to a possibility of metabolic disorders. Most of them are usually associated with encephalopathy and they may be depressed at birth. IEMs should always be considered even if there is a positive history of hypoxic ischemic encephalopathy. Presence of dysmorphic features could point to mitochondrial disorders or

---

BOX 2 IEMs presenting with seizures in neonatal period

1. Vitamin dependent seizures
   a. Pyridoxine dependency
   b. Pyridoxal phosphate dependency
   c. Folinic acid responsive seizures
2. Amino acid disorders, including neurotransmitter abnormalities
   a. GABA transaminase deficiency
   b. Nonketotic hyperglycinemia (glycine encephalopathy)
   c. Sulfite oxidase deficiency & molybdenum cofactor deficiency
3. Metal disorders like Menke's disease
4. Urea cycle disorders
5. Organic acidurias
6. Aminoacidurias
7. Mitochondrial disorders
8. Peroxisomal disorders

BOX 3 IEMs presenting as seizures in infancy, childhood and adolescence

1. Biotinidase deficiency
2. Methylmalonic acidemia
3. Hyperhomocysteinemia
4. Pyridoxine dependency (Children less than 3 years)
5. Glut-1 deficiency syndrome
6. Serine synthesis disorders
7. Creatine synthesis disorders
8. Purine metabolic defects
9. GABA transaminase deficiency
10. Carbohydrate deficiency glycoprotein disorders
11. Some of the progressive myoclonic epilepsies
    a. Myoclonic-epilepsy with ragged red fibers (MERRF)
    b. Ceroid lipofuscinoses
    c. Sialidoses

---

peroxisomal disorders. Burst-suppression pattern on EEG should also make one consider IEM in a given case. In older children presence of associated global developmental delay, involuntary movements, pigmentary changes, lens dislocation, abnormal body odor, skin and hair changes and organomegaly are important pointers to neurometabolic disorders.

Seizure Types

Table 1 correlates the typology of seizure with etiology of neurometabolic disorder. The neurometabolic disorders can present as various syndromic phenotypes with different seizure types such as early myoclonic encephalopathy, early infantile epileptic encephalopathy, infantile spasms, and myoclonic epilepsies. They have various degrees of treatability at present, with some requiring prompt diagnosis and intervention to avoid otherwise catastrophic outcomes. The common treatable disorders are mentioned in **Table 2**.

Glucose Transporter-1 (GLUT-1) Deficiency

Glucose transporter type I facilitates the passage of glucose across the blood-brain barrier, and its dysfunction in the developing brain leads to the development of a metabolic encephalopathy. CSF shows hypoglycorrhachia associated with normal plasma glucose and low-to-normal CSF lactate (CSF to blood glucose ration of less than 0.45), measured in a fasting state. A wide array of phenotypes has been associated with this disorder, but 90% of affected children develop epilepsy (of various types, including absence, focal, generalized myoclonic, clonic, tonic, and nonconvulsive status epilepticus). Microcephaly, ataxia, and psychomotor delay may be present, but patients may also suffer from epilepsy without any accompanying motor or cognitive deficiencies. EEG findings vary and may be normal, but usually include either focal or generalized

Table 1 Seizure types in neurometabolic disorders

Seizure type	Neurometabolic disorder
Infantile spasms	Biotinidase deficiency, Menkes disease, mitochondrial disorders, organic acidurias, amino acidopathies
Myoclonic seizures	Nonketotic hyperglycinemia, mitochondrial disorders, GLUT-1 deficiency, storage disorders, MERRF
Progressive myoclonic epilepsies	Lafora disease, mitochondrial disorders like MELAS and MERRF, Unverricht-Lundborg disease, sialidosis
Epilepsy with generalized tonic-clonic seizures	GLUT-1 deficiency, neuronal ceroid lipofuscinosis, other storage disorders, mitochondrial disorders
Epilepsy with myoclonic-astatic seizures	GLUT-1 deficiency, neuronal ceroid lipofuscinosis
Epilepsy with (multi-)focal seizures	Neuronal ceroid lipofuscinosis 3, GLUT-1 deficiency and others
Epilepsia partialis continua	Alpers disease, other mitochondrial disorders

Abbreviations: MELAS, mitochondrial encephalopathy with lactic acidosis and stroke-like episodes; MERRF, myoclonic epilepsy with ragged red fibers.

Table 2 Treatable neurometabolic disorders presenting as epilepsy

Condition	Therapy
GLUT-1 deficiency	Ketogenic diet
Cofactor-dependent epilepsy	Pyridoxine, pyridoxal phosphate, folinic acid, biotin
GAMT deficiency	Creatine supplementation, arginine-restricted, ornithine-enriched diet
Phenylketonuria	Low-phenylalanine diet; in atypical phenylketonuria substitution of L-DOPA, 5OH-tryptophan, folinic acid
Defects of serine biosynthesis	Serine supplementation
Disorders of CoQ biosynthesis	Coenzyme Q supplementation
Autosomal recessive methylene tetrahydrofolate reductase deficiency	Betaine and methionine supplementation

Abbreviation: GAMT, guanidinoacetate methyltransferase.

slowing or attenuation, or spike-and-wave discharges (generalized, focal, or multifocal). Neuroimaging results may demonstrate diffuse atrophy.

Glucose transporter I deficiency has emerged as the leading metabolic indication for the ketogenic diet, a dietary therapy that replaces glucose with ketone bodies as the primary biochemical energy source. Response is rapid, even in the case of formerly refractory seizures, and treatment should be maintained long-term. Additionally, there are certain compounds known to inhibit Glut-1, including phenobarbital, diazepam, methylxanthines (theophylline, caffeine), and alcohol, which should be avoided.

Pyridoxine, Folinic Acid, and Pyridoxal-5-Phosphate-dependent Epilepsies

There are various epileptic encephalopathies related to vitamin B_6 metabolism, and pyridoxine-dependent epilepsy (PDE) is the prototype, resulting from a loss of the biologically active pyridoxal-5-phosphate (PLP) due to a dysfunction of the protein antiquitin (ALDH7A1). PDE normally presents within the first hours following

birth with serial refractory seizures responsive to pyridoxine administration. Trials of systemic pyridoxine administration require close cardiorespiratory monitoring. Diagnosis is based on demonstrating increased levels of pipecolic acid and alpha-aminoadipic semialdehyde (AASA) in blood and CSF and genetic studies for *ALDH* gene. Improvement is significant and usually rapidly appreciable on EEG. Treatment is life-long, and the usual dose of pyridoxine is around 15 mg/kg/day up to 500 mg/day. Learning difficulties, particularly language, seem to be a common complication of early-onset pyridoxine-dependent epilepsy. Variants of the disorder that respond to folinic acid instead of, or in addition to, pyridoxine have also been described, as well as atypical cases with long symptomatic periods or presenting later in infancy (i.e., weeks or months following birth up to three years of age).

PNPO, or pyridox(am)ine phosphate oxidase, deficiency is a distinct disorder involving refractory seizures responsive not to pyridoxine but to its biologically active form, pyridoxal-5-phosphate (PLP). This disorder is due to a defect in the enzyme PNPO, which synthesizes PLP from precursors pyridoxine-P and pyridoxamine-P. Patients may present prenatally with fetal seizures and premature birth and if untreated can progress to status epilepticus and death. Laboratory and genetic testings are available to confirm these diagnoses. It is treated by administering pyridoxal phosphate at a dose of 10–50 mg/kg/day.

Nonketotic Hyperglycinemia

This disorder of defective glycine degradation presents in the neonatal period with lethargy, hypotonia, hiccups, ophthalmoplegia and disturbance of other vegetative functions of the brainstem. As the coma deepens, apnea and frequent, segmental, myoclonic jerks develop. Over the next few months, severe refractory epilepsy develops, with myoclonus as the initial major seizure type but evolving into infantile spasms or partial motor seizures. Severe mental retardation and tetraplegia also become evident. In the first days and weeks, the EEG shows no normal background activity, but bursts of epileptic sharp waves (so-called burst suppression pattern), changing to high voltage slow activity, and then to hypsarrhythmia by around three months if the infant survives. The diagnosis is suggested by an increased glycine concentration in all body fluids and by the demonstration of an elevated CSF to plasma glycine ratio (> 0.08); it can be confirmed by a decreased activity of the hepatic glycine cleavage system and mutation analysis. MRI can be normal or show agenesis or hypoplasia of the corpus callosum.

Specific treatment is not available although lowering of glycine by administration of sodium benzoate does improve survival. In several patients, therapeutic trials with NMDA antagonists have been reported, with some effects on EEG and seizure frequency. Severe epilepsy is the rule in surviving children and is treated by conventional antiepileptic drugs. Valproic acid should not be used from a theoretical point of view, as it will further inhibit the hepatic glycine cleavage system.

Disorders of Creatine Metabolism

Among the disorders of creatine metabolism, guanidinoacetate methyltransferase (GAMT) deficiency is regularly associated with epilepsy, which is often refractory to conventional treatment. Creatine supplementation alone frequently leads to improvement. In some patients, reducing the toxic compound guanidinoacetate by dietary reduction of arginine and supplementary ornithine has been found to achieve epilepsy control. Infants can present with West syndrome, with atypical absences, astatic and generalized tonic-clonic seizures being common later on. Imaging findings can be normal even in untreated adults; but in some patients, basal ganglia signal abnormalities can be found. A diagnosis of GAMT deficiency may be suspected, by demonstrating increased excretion

of guanidino compounds in urine and when the prominent creatine and creatine phosphate peak is absent on proton magnetic resonance spectroscopy (1H-MRS) of the brain or cerebrospinal fluid.

LABORATORY INVESTIGATIONS

The goal of various laboratory studies, including biochemical testing, may be to determine the extent and severity of organ or tissue involvement, to classify a presumed inherited metabolic problem according to the aspect of metabolism involved and to establish a specific diagnosis. The tests should proceed from simple, widely available screening tests to specific, definitive costlier second-line investigations.

The screening tests include hemogram to pick-up leukopenia or thrombocytopenia that may be associated with organic acidemia, estimation of liver and renal functional tests. All children with suspected IEMs should have frequent glucose monitoring, estimation of electrolytes, arterial lactate, arterial blood gases, ammonia and ketone bodies. Simple urine tests like dinitrophenylhydrazine test (DNPH), ferric chloride, silver nitroprusside test, Rothera test for ketone bodies, Benedict's test for reducing sugars and Seliwanoff test for fructosuria when positive can give vital clues to diagnosis and guide further specific tests. They can also guide appropriate treatment pending the results of the definitive second-line investigations.

In children who show some abnormalities in the routine screening tests or in whom the suspicion of IEM is very high second-line investigations can be ordered **(Box 4)**.

Points to Remember before Sending Samples

Sample should be collected before specific treatment is started or feeds are stopped as results may be falsely normal, if the child is off feeds. Samples like serum ammonia and lactate should be immediately tested. Lactate preferably arterial and 2 hours after feeding. Gas chromatography/mass spectrometry (GC/MS) is a test used mainly for nonpolar substances like organic acids and tests like high performance liquid chromatography (HPLC) and liquid chromatography-mass spectrometry-mass spectrometry (LC-MS-MS) is good for polar substances like amino acids and orotic acids. Depending on the clinical suspicion, appropriate tests should be ordered.

Role of MRI and MR Spectroscopy

Neuroimaging findings can aid in reaching a proper and prompt diagnosis of inborn errors of metabolism for an effective treatment and to obtain baseline studies to monitor the disease. These can at times be very conclusive when a paucity of the facilities and financial constraints prevent or delay the enzymology, histology and molecular studies. Neuroimaging can thus be an eye opener

---

BOX 4 Investigations for neurometabolic disorders

1. *Brain imaging:* Magnetic resonance imaging (MRI) is preferred to computer tomography (CT) scan of brain
2. Electrophysiological studies like brainstem evoked response audiometry (BERA), visual evoked potentials (VEP), somatosensor evoked potentials (SSEP), nerve conduction studies and electromyography (EMG)
3. Radiographs of hands, chest, spine
4. *Plasma aminoacidogram:* Thin layer chromatography (TLC) screening, quantitative if abnormalities are found
5. Urinary aminoacidogram by TLC/paper chromatography
6. HPLC (High performance liquid chromatography)
7. Tandem mass spectroscopy (TMS)
8. Urinary gas chromatography/mass spectroscopy (GC/MS)
9. Urinary MPS screening test
10. Urinary oligosaccharide screening test.

---

in the unexplained cases. Pattern of involvement of basal ganglia, dentate nucleus, white matter and cerebral/cerebellar atrophy provided important clues for the diagnosis. IEM may be associated with characteristic imaging findings.

- Diffuse cortical migration and sulcation abnormalities are seen in Zellweger syndrome.
- Agenesis of the corpus callosum is seen in pyruvate decarboxylase deficiency, Menkes disease and nonketotic hyperglycinemia.
- Brainstem and cerebellar edema are seen in Maple syrup urine disease.
- Subdural hematomas and frontotemporal atrophy giving characteristic 'bat-wing' appearance suggest glutaric aciduria.
- 3-Methylglutaconic aciduria type I is a rare inborn error of leucine catabolism that has extensive white matter disease.
- *Pyruvate dehydrogenase deficiency:* MRI of the brain shows complete or partial agenesis of the corpus callosum, heterotopic gray matter, the absence of the medullary pyramids and the abnormal inferior olives, hydrocephalus and cerebellar dysplasia.
- *Leigh's disease:* shows bilateral, symmetric, focal hyper-intensities in the basal ganglia, the thalamus, the substantia nigra, and the brainstem nuclei at various levels on the T2-weighted MRI images due to spongiform changes and vacuolation in the affected brain structures.

MR Spectroscopy

Magnetic resonance spectroscopy (MRS) provides a window on the intracellular metabolic events that occur in various neurometabolic disorders thereby giving vital clues to the diagnosis. MRS is a clinically useful, noninvasive tool for identifying the biochemical state of the CNS. MRS can be complementary to MRI by giving chemical pathology of MRI detected lesions and there is evidence that MRS may also detect abnormalities not revealed by MRI. MRS offers valuable information for the individual patient for his/her diagnosis and therapy when it is integrated fully into the clinical setting.

Metabolites measured with 1H-MRS include N-acetyl-aspartate (NAA), a neuronal marker; creatine (Cre) composed of phosphocreatine and creatine, which are bioenergetic metabolites; choline-containing compounds (Cho), including free choline and phosphoryl and glycerophosphoryl choline that are released during membrane disruption; lactate (Lac), which accumulates in response to tissue damage or anaerobic glycolysis; and other metabolites only seen when acquired with short echo time sequences, such as the neurotransmitters glutamate and immediately formed glutamine (Glx) and myoinositol (mI or Ins), an osmolyte and astrocyte marker.

Characteristic Patterns in Important Neurometabolic Disorders

a. In Canavan disease, MRS shows marked elevation of the NAA peaks. In addition to an elevated NAA peak, patients with Canavan disease have abnormally increased NAA/Cre and NAA/Cho ratios.
b. *Creatine deficiency:* Proton MRS shows reduced or absent creatine peak.
c. Pyruvate dehydrogenase (PDH) deficiency shows an elevated level of pyruvate at the 2.37 ppm.
d. *Leigh's disease:* In Leigh's disease and other mitochondrial disorders, MRS reveals an abnormally high lactate peak and a decreased NAA peak in the basal ganglia and occipital gray matter. This is demonstrated in MR spectroscopy as peak at 1.33 ppm.
e. *Adenoyl succinate lyase deficiency:* There is a characteristic accumulation of succinyladenosine (S-Ado) in the tissue and

in the body fluids. The in vivo proton MRS measurements show a prominent signal at the 8.3 ppm in the gray and white matter brain regions of all the patients that corresponds to the accumulated S-Ado.

f.   In phenylketonuria, elevated phenylalanine levels can be seen with MRS of the brain.

g.   *Nonketotic hyperglycinemia:* Proton-MR spectroscopy detects increased intracerebral levels of glycine, lactate, and creatine.

Role of Genetic Studies

Neurometabolic disorders are the inherited disorders with majority of them having autosomal recessive inheritance. Because they are common in consanguineously married couples, there is a risk of recurrence in the next sibling and genetic counseling is an important aspect while treating neurometabolic disorders. The role of pediatrician does not end at just diagnosis and treatment of the index child. The causative gene for most disorders is known and a genetic diagnosis should always be attempted in all cases. This will help in confirming the diagnosis in a given child and gives fool-proof technique for prenatal diagnosis. Prenatal diagnosis of neurometabolic disorders based on amniotic fluid analysis for metabolites are not very sensitive and specific.

TREATMENT

Comprehensive management of IEM includes both dietary treatment and pharmacotherapy. It is usually implemented by an interdisciplinary team consisting of metabolic pediatrician, pediatric intensivist, dietitian, nurses, occupational therapist and physiotherapist. There are certain simple principles that need to be followed while we manage a case of IEM.

1.   Treatment may have to be instituted empirically without a specific diagnosis
2.   Reduce formation of toxic metabolites by decreasing substrate availability (stopping feeds and preventing endogenous catabolism)
3.   To provide adequate calories
4.   To enhance excretion of toxic metabolites
5.   To institute co-factor therapy for specific disease and also empirically if diagnosis is not formed.

Management at tertiary center consists of cardiorespiratory support; nonresponse or worsening on supportive therapy: peritoneal dialysis, hemodialysis, exchange transfusion to get rid of toxic metabolites; specific therapy—special diets, vitamins; and genetic counseling and prenatal diagnosis.

Pharmacological Treatment

Detailed treatment of metabolic disorders is described in Section 3. We discuss a few pertinent points here:

- *Replacement of product*: This consists of reaction product replacement like creatine monohydrate in guanidinoacetate methyltransferase deficiency, arginine in argininosuccinic aciduria and L-serine in 3-phosphoglycerate dehydrogenase deficiency.
- Enzyme replacement therapy (ERT).
- Co-factor replacement therapy.
- Gene transfer therapy (Still experimental).

Co-factor replacement therapy It forms an important part of treatment of IEM. Co-factors are the vitamins and minerals that affect the catalytic properties of many enzymes. Vitamin dependency states result due to mutations in the enzyme protein that affects utilization or binding of the vitamin or mineral co-factor. Several hundred times the physiological requirement of vitamins and minerals are required to treat the vitamin dependency states. **Table 3** shows the various co-factors that are helpful in different IEMs.

Dietary therapy Restrict substrates which accumulate (form toxic metabolites) like phenylalanine in phenylketonuria. Replace essential nutrients that are not produced due to block in the metabolic pathway like cysteine in homocystinuria. Diet should be nutritionally adequate for growth and development. Dietary therapy should be started as early as possible. Some restriction is required throughout life in most situations.

IN A NUTSHELL

1.   Neurometabolic disorders have a varied presentation affecting the neurological system and other organ systems.
2.   Though individually rare, collectively they are not uncommon. A high index of suspicion is required for timely diagnosis and good outcome.
3.   Simple biochemical tests and neuroimaging give vital clues for a possibility of neurometabolic disorders that could be followed by definitive diagnostic tests like metabolic tests like mass spectrometry (tandem mass or urine gas chromatography) or genetic studies.
4.   Protocol-based intensive management is required for these disorders for a good final outcome.
5.   Always offer genetic counseling and prenatal diagnosis.

Table 3 Co-factors for treating neurometabolic disorders

Co-factor	Disorders
• Thiamine	• Maple syrup urine disease, pyruvate dehydrogenase deficiency & complex I deficiency
• Riboflavin	• Glutaric aciduria type I and II, complex I deficiency
• Pyridoxine	• Homocystinuria, pyridoxine dependency, xanthurenic aciduria, primary hyperoxaluria type I
• Pyridoxal PO_4	• Pyridoxamine 5-phosphate oxidase deficiency
• Cobalamin	• Methylmalonic academia
• Folic acid	• Some cases of homocystinuria
• Folinic acid	• Hereditary orotic aciduria, methionine synthase deficiency, cerebral folate transporter deficiency, Kearns-Sayre syndrome
• Biotin	• Biotinidase deficiency, holocarboxylase synthetase deficiency
• Pantothenic acid	• 3-methylglutaconic aciduria type III
• Nicotinamide	• Hartnup disease
• Coenzyme Q_{10}	• CoQ_{10} deficiency, mitochondrial cytopathies
• Ascorbic acid	• Hawkinsuria, tyrosinemia type III
• Vitamin E	• Abetalipoproteinemia, glutathione synthetase deficiency
• Tetrahydrobiopterin	• Disorders of BH_4 synthesis, BH_4 responsive forms of PKU

Chapter 42.26
Neurodegenerative Disorders
Naveen Sankhyan

Neurodegenerative disorders (NDDs) are characterized by loss of acquired milestones. The manifestations of neurodegeneration vary with age and depends on the area of neuraxis preferentially involved. The outcome of most childhood NDDs is dismal but a proper diagnosis is essential for genetic counseling, prenatal diagnosis and prognostication.

EPIDEMIOLOGY

The true burden of NDDs in India remains unknown, though most of the common NDDs have been reported from India. A recent single center laboratory-based study reported sphingolipidoses as the most frequently occurring lysosomal storage disorder followed by mucopolysaccharidoses. Disorders like megalencephalic leuko-encephalopathy with subcortical cysts have been reported to have high incidence in specific populations in India.

PATHOGENESIS

For most disorders, the precise process by which the abnormal enzyme activity or abnormal metabolite accumulation causes brain damage is yet be defined. Both intrinsic and extrinsic factors are thought to be involved in the pathogenesis. The basis for most neurodegeneration is a gene defect, usually causing a faulty gene product (mostly an enzyme). Due to lack of enzyme activity there is either a lack of essential products or transporters or an accumulation of toxic metabolites. The underlying gene defect either affects—all the neurons or functionally-related neurons. Certain disorders may preferentially involve part of the neuron structure, e.g., axon, myelin, etc. Exogenous factors that can aggravate neuronal injury include prolonged fasting, high protein load, fever, hypoglycemia, etc.

APPROACH TO DIAGNOSIS

Rule Out Treatable Causes and Pseudoregression

Though pseudoregression is only apparent after the complete history and examination, its evaluation is importance. We need to identify these causes to treat them early and to avoid unnecessary investigations, and allay parental anxiety. Regression can occur due to poorly controlled seizures, over-medication with anticonvulsants, intercurrent systemic illness, nutritional deficiency states and secondary neurological problems. In a static encephalopathy, conditions that can result in a loss of milestones are; development of joint contractures, seizures, or a new onset of movement disorder. Disabled children are also at risk for depression or other emotional problems. These psychological problems can lead to memory, mood changes and behavioral changes which may be interpreted as a sign of neuroregression. Loss of abilities can also occur due to nonhereditary treatable disorders like progressive hydrocephalous, hypothyroidism, retroviral infection, psychosocial stress or depression. In some parts of India, infantile tremor syndrome is common and infants who are predominantly breastfed suffer from vitamin deficiency state and present with typical cutaneous pigmentation, cognitive regression with or without tremors.

History and Examination

A detailed history is aimed at ascertaining the age of onset, and the areas of development affected. The disorder may predominantly affect motor milestones, vision, hearing, or cognition. The spheres of development involved indicate the possible areas in the neuro-axis and give a clue to the differential diagnosis **(Table 1)**. Since almost all disorders causing neuroregression are hereditary a family history of three generations is important to identify the mode of inheritance and to identify others at risk or mildly affected individuals. Certain findings in general physical and systemic examinations give an indication to the nature of disorder **(Table 1, Figs 1 and 2)**. After a detailed history and examination, we generally get a fair idea about the possible distribution of the pathological process within the nervous system **(Table 2)**. We would also know whether we are dealing with a pure neurological disorder or other organ systems are involved as well.

The overall goal is to arrive at a reasonable syndromic diagnosis (as below) to guide further testing. The age and the syndromic diagnosis then helps us to narrow down the differentials based on the most dominant positive and negative clinical features. Frequently, findings from the initial investigations also aid in considering differentials.
1. Gray matter degenerations
2. White matter degeneration—Leukodystrophies
3. Progressive ataxias
4. Basal ganglia disorders
5. Multisystem disorders with neuroregression

Regression in a Child below Two Years (Flow chart 1)

Disorders that have very early onset often have profound and rapid effects on development. The child frequently has delayed

Table 1 Clinical features of gray and white matter diseases

Features	*Gray matter*	*White matter*
Loss of social interaction and cognitive abilities	Early	Late
Seizures	Early and prominent	Late
Retinitis pigmentosa	May be present	Absent
Primary optic atrophy	Rare	May be seen
Primary neuropathy	Rare	May be seen
Imaging (MRI)	Cortical atrophy, abnormalities in basal ganglia, cerebellum (in those with specific involvement of these structures)	Clearly identifies abnormalities in white matter [may yield specific diagnostic findings]
Electroretinogram (ERG)	May be abnormal	Normal
Visual evoked response (VER)	May be abnormal	Normal
Brainstem auditory evoked responses (BAER)	Usually normal	Abnormal
Figures 1A and B Axial T2W MR scan showing cerebellar atrophy (A) and extensive conjunctival telangiectasias in a child with Ataxia telangiectasia (B)

milestones and then regresses further. Often due to lack of any clear acquired milestones, the loss of milestones may be difficult to appreciate. Most commonly, the baby would not have visual fixation, social interaction or any head control or voluntary reaching. Other common symptoms include seizures, irritability or lethargy, hypotonia, feeding difficulties and/or vomiting, and/or failure to thrive.

Beyond the first year of life, the loss of milestones becomes easier to identify. Loss of motor milestones is often an early sign of neurodegeneration in this group. The loss of motor abilities may result from corticospinal, cerebellar, extrapyramidal or motor unit involvement. During the second year of life disorders with neuro-visceral storage (mucopolysaccharidosis and mucolipidosis) also begin manifesting with gradually increasing dysmorphism, skeletal abnormalities and cognitive decline. Pure neurological deterioration with prominent seizures and vision loss is evident at this age in children with neuronal ceroid lipofuscinosis (NCL). Yet another group of children presents with recurrent neurological deterioration interspersed with apparent recovery (organic aciduria, mitochondrial disorders, urea cycle disorders, etc.). Disorders like Rett syndrome are characterized by peculiar loss of purposeful hand movements and acquired microcephaly in girls.

Neuroregression Beyond 2 Years and in Adolescence (Flow charts 2 and 3)

In children beyond the age of two years the onset of NDDs is easier to identify. The traditional clinical distinction between the phenotypes of NDDs like white matter, gray matter disorders, and cerebellar degenerations are much evident now. The mimickers of NDDs in older children include disorders previously discussed and also SSPE (subacute sclerosing pan-encephalitis), presenting with behavioral changes, cognitive deterioration with or without myoclonic jerks. Another important aspect of disorders presenting later in childhood is the wide variation in symptomatology. The variability is evident in both recessively (Wilsons disease, GM1, GM2 gangliosidosis) and dominantly inherited disorders (Spinocerebellar ataxia, Huntington's disease).

INVESTIGATIONS

Imaging

A high resolution MR imaging with spectroscopy (MRS) is the desirable investigation. In certain children, it may provide a diagnostic clue, e.g., Pantothenate kinase-associated neuro-degeneration (PKAN) with *eye of tiger* sign in globus pallidi **(Fig. 3)**, adrenoleukodystrophy **(Figs 4A and B)**, and glutaric aciduria **(Fig. 5)**. MRS helps in diagnosis of certain disorders such as Canavan, mitochondrial encephalopathies **(Figs 6A to C)**, and creatine deficiency disorders. Neuroimaging also guides to further work-up of a child by showing suggestive findings [Wilson disease, metachromatic leukodystrophy **(Fig. 7)**] or excluding certain conditions which have characteristic findings.

Plain radiographs of bones are important in suspected neuro-visceral storage including mucopolysaccharidosis, mucolipidosis, gangliosidosis, fucosidosis and others **(Figs 8A and B)**.

Biochemical Tests

Urine and blood assay for plasma ammonia, blood lactate and pyruvate, plasma amino acids, urine organic acids, blood acylcarnitine guide the evaluation of child with suspected neurometabolic disorder.

Electrophysiological Tests

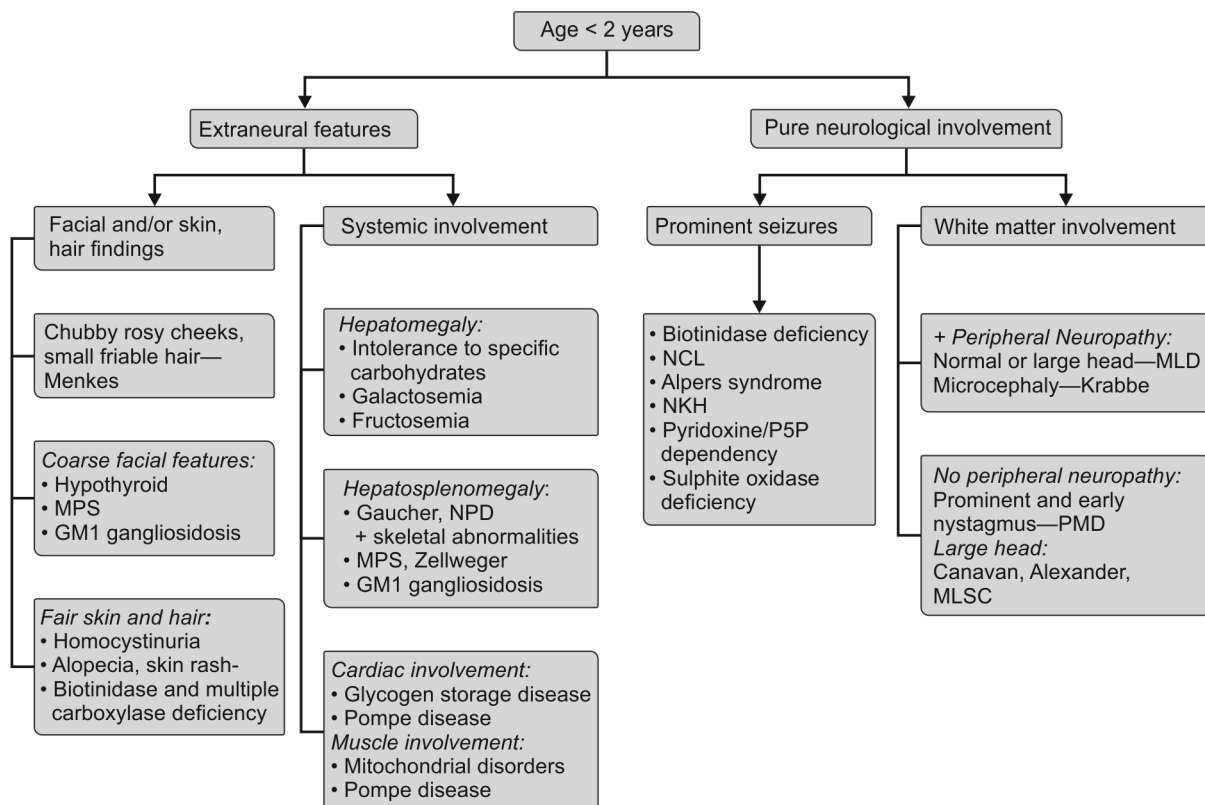
These include VEP, BAER, NCS, EEG, EMG, and somatosensory evoked potentials. These may help delineate the extent of central and peripheral nervous system involvement in the patient.

Figures 2A and B Axillary excoriated rash (A) and alopecia and scalp seborrhea (B) in a child with biotinidase deficiency

Table 2 Some clinical pointers in hereditary neurodegenerative disorders

Organ/features	Abnormality	Disorders
Head	Microcephaly	NCL, Krabbe disease, Rett syndrome
	Macrocephaly	MPS, Alexander, Canavan, GM1 gangliosidosis, Tay-Sachs disease, MLSC
Hair	Alopecia	Biotinidase deficiency
	Pigmentary changes	PKU, Menkes
	Wooly, kinky hair	Menkes
Skin	Rash	Biotinidase, holocarboxylase deficiency
	Subcutaneous nodules	Farber disease
	Angiokeratomas	Fabry disease
	Fat pads, focal atrophy	Congenital disorders of glycosylation
	Hyperpigmentation	Adrenoleukodystrophy
Eyes	Cataract	Galactosemia, Zellweger, Wilson disease
	Retinitis pigmentosa	Peroxisomal disorders, NCL, mitochondrial encephalomyopathies, MPS, PKAN, ABLP
	Cherry red spot	Tay-Sachs disease, Niemann-Pick, GM1 gangliosidosis
	Optic atrophy	NCL, MLD, Krabbe, Canavan, GM2 gangliosidosis
Ears	Deafness	MPS, ALD, Mitochondrial disorders
	Hyperacusis	Krabbe, Tay-Sachs
Abdomen	Hepatosplenomegaly	MPS, GM1 gangliosidosis, Gaucher, Niemann-Pick
	Hernia	GM1 gangliosidosis, MPS
Nervous system	Peripheral neuropathy	MLD, Krabbe, Mitochondrial disorders, Niemann-Pick
	Hydrocephalous/raised Intracranial pressure	MPS, Infantile Alexanders
Cardiac	Cardiomyopathy	FAOD, mitochondrial disorders, Friedreich ataxia, AVED, Pompe disease
	Valvular defects	MPS, Zellweger, Fabry

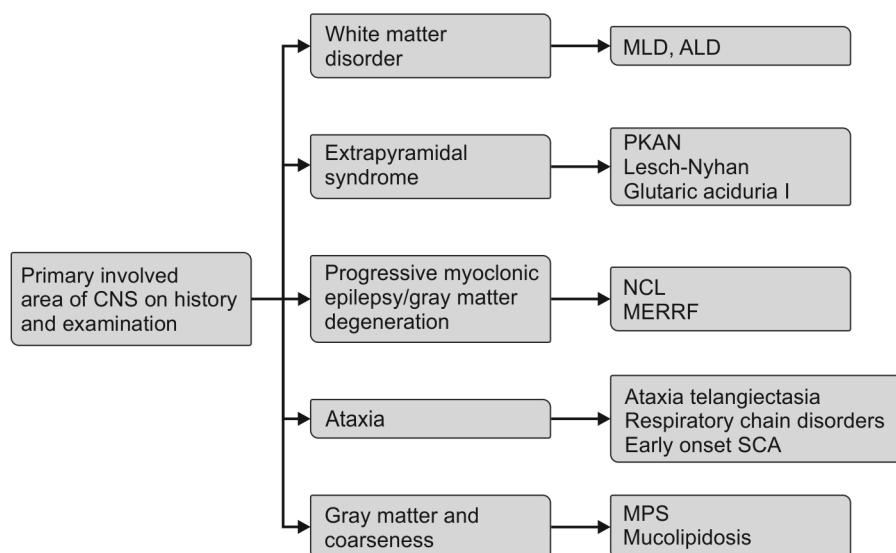
Abbreviations: NCL, neuronal ceroid lipofuscinosis; MPS, mucopolysaccharidosis; PKU, phenylketonuria; PKAN, pantothenate kinase-associated neurodegeneration; ABLP, abetalipoproteinemia; MLD, metachromatic leukodystrophy; ALD, adrenoleukodystrophy; FAOD, fatty acid oxidation defects; AVED, ataxia with vitamin E deficiency; MLSC, megalencephalic leukodystrophy with subcortical cysts

Flow chart 1 Approach to progressive neurological deterioration in a child less than 2 years of age


Abbreviations: MLD, metachromatic leukodystrophy; PMD, Pelizaeus-Merzbacher disease; NCL, neuronal ceroid lipofuscinosis; MLSC, megalencephalic leukodystrophy with subcortical cysts; MPS, mucopolysaccharidosis; NPD, Niemann-Pick disease; P5P, pyridoxal 5 phosphate; NKH, Nonketotic hyperglycinemia.

Flow chart 2 Approach to progressive neurological deterioration in two to five years age group

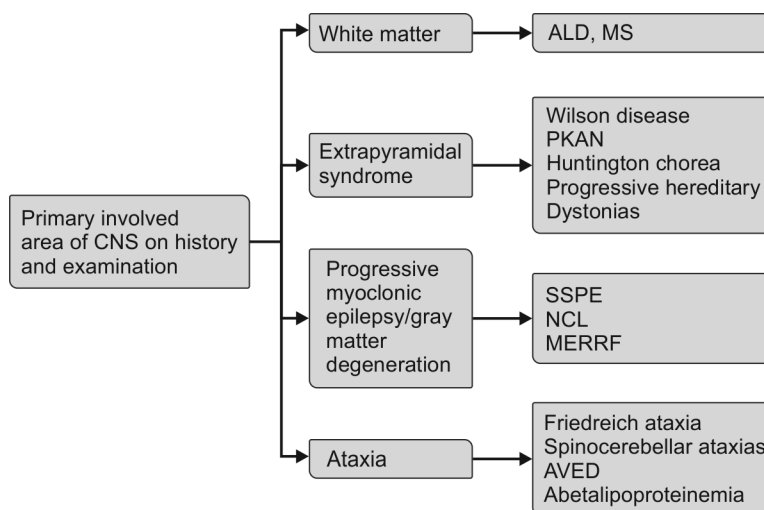
Primary involved area of CNS on history and examination →

- White matter disorder → MLD, ALD
- Extrapyramidal syndrome → PKAN / Lesch-Nyhan / Glutaric aciduria I
- Progressive myoclonic epilepsy/gray matter degeneration → NCL / MERRF
- Ataxia → Ataxia telangiectasia / Respiratory chain disorders / Early onset SCA
- Gray matter and coarseness → MPS / Mucolipidosis


Abbreviations: MLD, metachromatic leukodystrophy; NCL, neuronal ceroid lipofuscinosis; ALD, adrenoleukodystrophy; MERRF, myoclonic epilepsy with ragged red fibers; PKAN, pantothenate kinase-associated neurodegeneration; SCA, spinocerebellar ataxia

Flow chart 3 Approach to progressive neurological deterioration in five to fifteen years age group

Primary involved area of CNS on history and examination →

- White matter → ALD, MS
- Extrapyramidal syndrome → Wilson disease / PKAN / Huntington chorea / Progressive hereditary Dystonias
- Progressive myoclonic epilepsy/gray matter degeneration → SSPE / NCL / MERRF
- Ataxia → Friedreich ataxia / Spinocerebellar ataxias / AVED / Abetalipoproteinemia


Abbreviations: ALD, adrenoleukodystrophy; MS, multiple sclerosis; SSPE; subacute sclerosing panencephalitis; MERRF, myoclonic epilepsy with ragged red fibers; PKAN, pantothenate kinase-associated neurodegeneration; NCL, neuronal ceroid lipofuscinosis; AVED, ataxia with vitamin E deficiency.

Hematology and Histopathology

Peripheral smear provides supportive evidence in the form of vacuolated lymphocytes (NCL, Niemann-Pick disease, Pompe disease, GM1 gangliosidosis) or acanthocytes (PKAN, abetalipo-proteinemia, neuroacanthocytosis). Bone marrow examination demonstrates storage cells in Niemann-Pick disease, and Gaucher disease. Conjunctival, skin, and rectal biopsy help in the diagnosis of neuronal ceroid lipofuscinosis. Hair microscopy is diagnostic for Menkes disease **(Figs 9A and B)**.

Specific Investigations

These are done based on clues from preceding investigations; Serology for HIV, SSPE; Urine copper and serum ceruloplasmin for Wilson disease; Urine MPS for mucopolysaccharidosis; Enzyme analysis for lysosomal storage disorders, biotinidase deficiency; VLCFA and plasmalogen levels for peroxisomal disorders; and Mutation testing if the diagnosis is certain and the test is available.

TREATMENT

The first priority is to identify treatable causes of neuroregression like hydrocephalous, HIV infection, hypothyroidism, lead toxicity, etc. Specific treatment is available for many neurodegenerative disorders **(Table 3)**. Newer treatment options are now available. The child should be referred to a center with treatment facilities to ensure timely intervention.
Figure 3 Bilateral symmetrical hypointensities in the globus pallidi on axial T2W images in a child with PKAN
Figures 4A and B Axial MR scan of the brain, T2W images (A) showing posteriorly dominant, symmetrical, white matter hyperintense signal changes in a child with adrenoleukodystrophy. Note the characteristic peripheral contrast enhancement on postcontrast T1W image (B)
Figure 5 T2W MR scan of brain axial sections showing bilateral striatal hyperintensities, frontal white matter hyperintensities and frontotemporal atrophy with open operculam in a child with glutaric aciduria type 2
Figures 6A to C Axial T2W MRI in a child with Leigh's syndrome showing hyperintense signal changes (black arrows) in the medulla, cerebellum (A), midbrain (B), and bilateral basal ganglia (C)
Figure 7 Symmetrical hyperintensities on axial FLAIR MR images in periventricular white matter of a child with MLD
Figures 8A and B Wrist X-ray (A) showing epiphyseal changes (white arrow), and proximally tapered carpal bones (white arrowhead), the vertebral bodies show anteroinferior beaking in a child with mucopolysaccharidoses

Table 3 Few examples of treatment in neurodegenerative disorders

Disease	Therapeutic agent
Gaucher disease	Enzyme replacement, Miglustat
Fabry disease	Enzyme replacement
Attenuated variants of MPS I	Enzyme replacement
Pompe disease	Enzyme replacement
Ataxia (CoQ deficiency)	Coenzyme Q10
Ataxia with vitamin E deficiency	Vitamin E
Minimally symptomatic X-linked adrenoleukodystrophy	Bone marrow transplant
MPS 1H-Hurler disease	Bone marrow transplant
Glycogen storage disease	Liver transplant
Glutaric aciduria–II, Biotinidase deficiency	Co-factor replacement

Supportive Measures

Supportive treatment adds significantly to the quality of life of a child with NDD. Measures to reduce spasticity, control seizures, control pain, improve nutrition, prevent constipation, prevent bed sores, and to enhance mobility all contribute to the quality of life of the patient and indirectly to the quality of life of the parents and any unaffected siblings.

PROGNOSIS

The prognosis in neurodegenerative disorders depends on the underlying disorder. The prognosis of a NDD should be discussed only after confirming the diagnosis. While prognosticating the variability in disease progression should be kept in mind. In general an earlier onset of disease predicts a poorer outcome. However, several late onset diseases can also rapidly progress, e.g., adrenoleukodystrophy.

PREVENTION

All efforts should be taken to establish an accurate diagnosis and offer prenatal diagnosis to prevent further children being affected by the same disease. The diagnosis may also help identify pauci or presymptomatic siblings or other family members who may benefit from early therapy, e.g., zinc therapy in Wilson disease. It would be wise to refer the parents for prenatal diagnosis to an equipped center before they plan any future pregnancies.

SELECTED NEURODEGENERATIVE DISORDERS

WHITE MATTER NEURODEGENERATIVE DISORDERS

Krabbe Disease

Globoid cell leukodystrophy or Krabbe disease is an autosomal recessive disorder caused by the deficiency of a lysosomal enzyme galactosylceramidase. It is an early onset, rapidly progressive and invariably fatal disease of infants. Late onset childhood and adult forms have also been described. In the most common form the *early infantile type*, onset is between 3 months and 6 months of age. The disease begins with generalized hyperirritability, hyperesthesia, episodic fever, over response to stimulation. This progresses rapidly to a stage of severe motor and mental deterioration, deep tendon reflexes (DTRs) are at first increased, then decreased, optic atrophy, decreased head growth are soon evident. The disease progresses to a state of burn out leaving the child decerebrate and blind.

In the late infantile type the child is normal during first year, then develops ataxia, weakness, spasticity, dysarthria, visual loss with optic atrophy. The disease course is slower compared with the infantile variety.

In the Juvenile onset (4–19 years) and adult onset (> 20 years) the disease manifests as slowly progressive spastic tetraplegia, optic nerve pallor, pes cavus, and sensory motor demyelinating neuropathy. Mental functions are preserved in around 50% of affected the patients. The hallmark of this disease on investigations is the presence of demyelinating polyneuropathy and raised CSF proteins. In early onset disease, MR imaging demonstrates high signal intensity in periventricular white matter with sparing of peripheral white matter in early stage. Signal abnormality in hilus of dentate nucleus, cerebellar WM and pyramidal tracts in the brainstem in an infant of few months are characteristic of Krabbe disease.

Pelizaeus-Merzbacher Disease

Pelizaeus-Merzbacher disease (PMD) is a X-linked hypomyelinating leukodystrophy. It is caused by the deficiency of proteolipid protein (PLP), an important myelin protein. PMD exhibits a broad clinical continuum. The most severe variant being the connatal variant of PMD, and the least severe being the pure form of Spastic Paraplegia Type 2. Classic PMD begins in first months of infancy with abnormal eye movements; rapid, irregular, small or large amplitude oscillations either vertical or horizontal. This is followed by slow development of spasticity, ataxia and involuntary movements. With disease progression, optic atrophy and seizures occur. Mental abilities usually are relatively preserved. Children with connatal form of PMD present shortly after birth and have an aggressive clinical course. Patients develop severe hypotonia, extrapyramidal signs, stridor and feeding difficulties. Death occurs within few months to years. X-linked form of spastic paraplegia that occurs either as a pure form, consisting of a slowly progressive paraplegia involving only lower limbs; or as a complicated form, in which spastic paraplegia occurs along with other features of PMD like nystagmus, dysarthria and ataxia.

Alexander Disease

Alexander disease is caused by mutation in the gene encoding glial fibrillary acidic protein. This condition begins in the first year of life with intellectual deterioration, macrocephaly, spasticity and seizures. Juvenile and adult forms also occur. The juvenile form often has no macrocephaly but bulbar and pseudobulbar signs of swallowing and/or speech difficulty occur frequently. The adult onset form has variable clinical features, and can resemble multiple sclerosis. Ataxia, quadriparesis, palatal myoclonus and other brainstem signs are prominent.

MRI shows diagnostic findings. It reveals extensive white matter changes with frontal predominance, a periventricular rim of altered signal intensity. The peripheral white matter is affected early in course of the disease. In late stages, cysts may develop. Bilateral, symmetrical, frontal white matter involvement involving the U-fibers in a macrocephalic patient is quite specific for Alexander disease, particularly if it extends posteriorly to involve the caudate heads.

Canavan Disease

Canavan disease is an autosomal recessive disorder characterized by spongy degeneration of white matter of the brain. It is caused by deficiency of enzyme aspartoacylase, leading to excessive

accumulation of N-acetyl aspartic (NAA) acid in the brain, especially in the white matter, with massive urinary excretion of NAA. The onset of this disease is between 3 months and 6 months of age with progressive macrocephaly, severe hypotonia, and persistent head lag. Later these children become hyper-reflexic and hypertonic. Seizures and optic atrophy occur. Most patients die in first decade of life. Neuroimaging shows diffuse symmetric abnormalities of cerebral white matter, including early involvement of subcortical white matter without any lobar predominance Globus pallidi involvement in association with diffuse white matter disease including the subcortical, deep, and periventricular regions suggests a diagnosis of Canavan disease. Magnetic resonance spectroscopy demonstrates a significant elevation of NAA peak and increase in NAA-to-choline ratio in cerebral white matter. The urinary and blood NAA levels are elevated.

Metachromatic Leukodystrophy

Metachromatic leukodystrophy (MLD) is an autosomal recessive disorder of myelin metabolism caused by deficiency of arylsulfatase A, or exceptionally, to a defect of nonenzymatic protein activator SAP 1. MLD most often occurs in the late infantile period usually in the second year of life, but less aggressive forms appear in late childhood and adolescence, and in adults. The *Late Infantile form* is the most frequent form of MLD, representing 60–70% of all cases. It is usually manifest between 1 and 2 years of age, with gait disturbance, ataxia, or weakness. Hypotonia may be the only and earliest sign. The most striking clinical finding in this stage is the absence of deep tendon reflexes, because of peripheral nerve involvement. Nerve conduction velocities are markedly decreased suggesting demyelination. Briefly, during the early stages, the mental status is normal and there is no vision impairment. But soon the neuroregression progresses to cause decerebrate posturing, genu recurvatum, optic atrophy and loss of speech develop; seizures occasionally occur. Death usually occurs between the ages of 3 years and 7 years. In the juvenile form symptoms begin between 5 years and 10 years of age. Deterioration in school performance and personality changes may be herald the onset of the disease. This is followed by gait problems, urinary incontinence and dysarthria. During the terminal stages, episodes of decerebrate posturing and generalized tonic clonic seizures occur. Death occurs by mid-adolescence. The adult form of MLD presents with dementia between the 3rd and 4th decades of life. Abnormalities in memory, psychiatric features, and personality changes are prominent features. There may be accompanying corticobulbar, corticospinal, and cerebellar changes.

Diagnosis

Urine examination for metachorochromatic granules is a useful preliminary test. Thin layer of urinary sediment demonstrates marked increase in sulfatide levels. Nerve conduction studies demonstrate demyelnation of motor and sensory nerves. The protein content of CSF is elevated up to 150–300 mg/dL. The MRI reveals symmetrical confluent areas of T2 hyperintensity in periventricular white matter with posterior predominance and initial sparing of subcortical U-fibers **(Fig. 7)**. The *tigroid* and *leopard skin* patterns of demyelination, which suggest sparing of the perivascular white matter, can be seen in the periventricular white matter and centrum semiovale. The corpus callosum, internal capsule, and corticospinal tracts are also frequently involved.

Megalencephalic Leukoencephalopathy with Subcortical Cysts

Megalencephalic leukoencephalopathy with subcortical cyst (MLC) was first described by van der Knaap in 1995. Molecular genetic testing has demonstrated mutations in *MLC 1* gene, which is located at chromosome *22qtel*. The inheritance of this disorder is autosomal recessive. It is a disorder, which is remarkable for its relatively mild neurological signs and symptoms in the setting of a very abnormal imaging study. It is characterized by delayed milestones, macrocephaly, a slow neurological deterioration with dysarthria and ataxia. Seizures, unusual in leukodystrophies are commonly reported. In India, this condition has been predominantly reported from the Agarwal community. MRI is diagnostic. It demonstrates diffusely hyperintense white matter (T2, FLAIR) of subcortical regions. The central white matter is spared; especially corpus callosum and occipital lobes. Subcortical cysts best appreciated on the FLAIR MRI sequences are seen in temporal and frontal lobes.

X-linked Adrenoleukodystrophy

X-linked adrenoleukodystrophy is characterized by two distinct phenotypes: adrenomyeloneuropathy and cerebral demyelinating form of adrenoleukodystrophy. Both result from the mutation of the *ABCD1* gene. The cerebral demyelinating form of adrenoleukodystrophy is the most severe manifestation of this disorder. The onset is during school age or later in adulthood. Prominent clinical features include emotional liability, hyperactive behavior, school failure, visual failure, accompanied by lower limb spasticity, gait problems, and auditory impairment. Rapid dementia and seizures often occur. This results in a vegetative state within 2–4 years, and to death at varying intervals thereafter. Adults and children can have adrenal insufficiency that can precede the onset of neurological symptoms. The MRI findings are generally characteristic showing initial lesions in splenium of the corpus callosum and then the white matter of the parieto-occipital lobes **(Figs 4A and B)**.

GRAY MATTER DISORDERS

Certain disorders resulting in gray matter degeneration with marked systemic manifestations have been already discussed in Section 3 (Mucopolysaccharidosis, Gaucher's disease, Niemann-Pick Disease, Gangliosidoses) and Section 21 (Rett syndrome). Ataxia telangiectasia is already described in an earlier chapter in this Section. Others are detailed below:

Menkes Disease

Menkes disease is an X-linked recessive disorder of copper transport caused by diverse mutations in a copper transporting ATPase, ATP7A. Menkes disease typically presents in boys in infancy with loss of previously attained developmental milestones, hypotonia, seizures and failure to thrive. Skin and hair changes are characteristic. The scalp hair is classically short, sparse, light colored, coarse, and twisted. Light microscopy will illustrate the pathognomonic *pili torti* (180° twisting of the hair shaft) and often other abnormalities **(Figs 9A and B)**. The hair tends to be lightly pigmented but in some cases they can be normally pigmented as well. Tooth eruption is delayed. The skin often appears loose and redundant. Neurologically, severe hypotonia and poor head control are nearly always evident. Muscle stretch reflexes are often hyperactive. Seizures including infantile spasms are common and often refractory to treatment. Subdural hematomas are common **(Figs 9A and B)**. Pelvic ultrasonography reveals diverticula of the urinary bladder in nearly all children. Radiographs often disclose abnormalities of bone formation in the skull (wormian bones), long bones (metaphyseal spurring) and ribs (anterior flaring, multiple fractures). This disease should be considered as a differential diagnosis in boy with suspected battered baby syndrome. This is a severe neurological disease and in those with classical disease death usually occurs by 3 years of age.

Tay-Sachs Disease

Tay-Sachs disease is caused autosomal recessive disease caused by hexosaminidase-A deficiency. Tay-Sachs disease presents in early infancy as hypotonia and delayed milestones, associated with progressive macrocephaly, an exaggerated startle response, and cherry-red spots at the macula. Cherry red spots are seen in around 90% of the affected babies. Importantly there are no organomegaly or bone changes. This is a severe neurodegenerative condition with most children dying in early childhood. Late onset forms are less common and progress more slowly. They present with progressive ataxia, psychosis, or progressive muscular atrophy. Cognitive impairment and deterioration is also common.

Neuronal Ceroid Lipofuscinosis

The neuronal ceroid lipofuscinoses (NCLs) are a group of inherited, neurodegenerative, lysosomal storage disorders. These disorders are characterized by progressive intellectual and motor deterioration, visual failure and seizures. *As a rule these group of disorders do not result in organomegaly, bone changes, or any coarsening of facial features.* Clinical phenotypes have been characterized traditionally according to the age of onset and order of appearance of clinical features into infantile, late-infantile, juvenile, adult, forms. However, there is considerable genetic and phenotypic heterogeneity. The same mutation can cause disease phenotype that is infantile onset and juvenile onset. Though the prevalence of various forms varies from region to region, the most prevalent NCLs are classic juvenile (CLN3 disease) and classic late infantile (CLN2 disease).

In the *classic late infantile* (CLN2) form, the first symptoms typically appear between age 2 years and 4 years, usually starting with seizures (myoclonic, generalized), followed by regression of developmental milestones, ataxia, and pyramidal signs. Visual impairment typically appears at age four to six years and rapidly progresses. Death usually occurs before teenage.

In the *classic juvenile* (CLN3 disease) form the onset is usually between ages four years and ten years. Rapidly progressing visual loss resulting in severe visual impairment within one to two years is often the first clinical sign. Many a time the children first report to an ophthalmologist for visual failure. Epilepsy with generalized tonic-clonic seizures and/or complex-partial seizures typically appears around age ten years. The loss of cognitive functions and intelligence occurs late and is slower in progression. The course may be variable and life expectancy ranges from the late teens to the forth decade.

Leigh Syndrome

Leigh syndrome is a group of severe neurodegenerative disease. The onset of Leigh syndrome typically occurs in infancy or early childhood. It typically manifests by rapid deterioration. In most cases, children do not display any dysmorphic features. However, various nonspecific abnormalities like prominent forehead and large ears might be observed. The onset of Leigh syndrome is often triggered by acute infections. Initial signs may include developmental regression with loss of previously acquired milestones. Other features include hypotonia or spasticity, dystonia, seizures, ataxia, dysphagia, ptosis, and abnormal eye movements such as nystagmus or slow saccades, breathing irregularities such as apnea. Further symptoms are failure to thrive and feeding difficulties.

In many children, the onset of symptoms is followed by a rapid deterioration and often death in infancy. Hallmarks of the disease are symmetrical lesions in the basal ganglia or brainstem on MRI imaging findings consists of bilateral, symmetrical hyperintensities on T2-weighted images **(Figs 6A to C)**. The lesions are commonly found in the basal ganglia, or in variable areas within the brainstem. They can also appear within several other CNS regions, such as the cerebellum, the thalamus and the spinal cord.

Numerous causative mutations in mitochondrial and nuclear genes, encoding components of the oxidative phosphorylation system have been described in the past years. Moreover, dysfunctions in pyruvate dehydrogenase complex or coenzyme Q_{10} metabolism may be associated with Leigh syndrome. Till date, there is no cure for affected patients, and treatment options are mostly unsatisfactory.

Wilson Disease

Wilson disease (WD) is caused by mutations in the *ATP7B* gene. WD begins with a presymptomatic period during which there is accumulation of copper in the liver that will cause hepatitis and, without treatment, will progress to liver cirrhosis and development of extrahepatic symptoms. The first neurologic symptoms of WD are commonly changes in behavior, deterioration in school performance, change in handwriting, dysarthria, drooling, tremor, or dystonia. The neurologic manifestations can be distinguished into three main phenotypes:

Dystonic Syndrome

It manifests as choreoathetosis and dystonic posturing. The dystonia may start slowly, focally and initially only during performing an action but soon progresses to other parts of body to become generalized. The involvement of facial muscles results in a fixed sardonic smile. Dysarthria results in a change in voice quality and occurs early in the disease course.

Parkinsonian Syndrome

The patient presents with rigidity and bradykinesia. Voice change and lack of facial expression are also prominent. Gait is unsteady with small steps, reduced postural reflexes, festination, and freezing.

Tremor Type

This phenotype is characterized by postural and action tremor with high amplitude and low frequency. Its proximal component can be well observed when a patient's arms are outstretched, showing the *wing-beating tremor*. It is sometimes associated with cerebellar syndrome.

Other Extrahepatic Features

Kayser-Fleischer (KF) rings on the cornea are detected by slit-lamp examination in most children with neurological manifestations. Other eye findings include sunflower cataracts and oculomotor abnormalities. Other extrahepatic features include renal stones, renal tubular acidosis, hemolytic anemia, osteoarticular disorders, myocardial abnormalities and endocrine disturbances.

Pantothenate Kinase-associated Neurodegeneration

Previously called Hallervorden-Spatz disease, pantothenate kinase-associated neurodegeneration (PKAN) is a recessive autosomal disease caused by a mutation of the gene (20p13–p12.3) encoding pantothenate kinase 2 (PANK2), an essential mitochondrial enzyme involved in coenzyme A biosynthesis. PKAN classically begins with gait abnormalities, generally before the age of 6 years. Dystonic posturing is often prominent, it can be asymmetric. Others symptoms include dysarthria, extrapyramidal syndrome, cognitive deterioration, or a neuropsychiatric disorder. About two-thirds of patients have clinical or electroretinographic

evidence of retinopathy manifesting as retinitis pigmentosa. Some children may have an atypical presentation with later onset (teenage) and slower progression. Classic and atypical PKAN patients show the same findings on brain MRI. In globus pallidus, the *eye of the tiger* sign consists of bilateral areas of hyperintensity (corresponding to necrosis tissue) surrounded by a ring of hyposignal (high iron) on T2-weighted sequences **(Fig. 3)**.

IN A NUTSHELL

1. A thorough clinical evaluation that includes a detailed history, family history, general physical, neurological and systemic evaluation forms an important starting point for evaluation of NDDs.
2. The investigations are planned to support and later confirm the diagnosis. Diagnostic testing can be undertaken as per clues obtained from history and examination, e.g., HIV testing, urine mucopolysaccharidosis, VLCFA, etc.
3. Treatable causes should be excluded first. Supportive therapy should be undertaken in all children to make the child's life comfortable, e.g., control seizures, spasticity, adequate nutrition and skin care, etc.
4. The ultimate goal of clinical evaluation and investigations is to offer preventive diagnosis for future children and possibly identify and treat pre or pauci symptomatic individuals in the family.

Chapter 42.27
Spinal Cord Disorders
Vykunta Raju KN

The diagnosis and treatment of pediatric spinal disorders differs significantly from that of adult spinal disorders. If we recognize and treat spinal cord disorders, permanent severe neurologic disability can be minimized. A wide variety of congenital, developmental, traumatic and neoplastic disorders may occur in children. Given the rapid growth that occurs in children, problems in the spine may become evident due to the development of scoliosis, pain, or neurological problems such as weakness or numbness. Unlike adult treatments, the surgical treatment of these disorders in children must take into account the expected growth and development of the spine.

EPIDEMIOLOGY

Spinal cord injuries (SCIs) and myelomeningocele are two most common pediatric spinal cord disorders. Neural tube defects are the most common congenital malformation and their incidence in North India is as high as 3.9–9/1000 live births and may be higher in still births. Neural tube defects are discussed in the chapter on neural tube defects.

ANATOMY OF SPINAL CORD

The spinal cord lies within the vertebral canal. It extends from the foramen magnum, where it joins medulla to the level of the first or second lumbar vertebra. Disparity exists between vertebral and segmental cord level with age, at birth it lies at L2 vertebrae. It is oval in shape, and has two enlargements in the cervical and lumbar regions corresponding to the outflow of nerves to the limbs. At its lower end, it terminates in the conus medullaris, from the end of which a delicate filament, the filum terminale, continues downwards to the posterior surface of the coccyx. The spinal cord is regarded as being organized into segments, one corresponding to each pair of spinal nerves. There are 8 cervical, 12 dorsal or thoracic, 5 lumbar, 5 sacral segments, and 1 coccygeal. Since spinal cord ends at the first or second lumbar vertebra, all the spinal nerves below the first lumbar descend to their respective foramina in a bundle of nerves known as the cauda equina.

The spinal cord, like the brain, is surrounded by three meninges, pia mater, arachnoid and dura mater. On the transverse section, the cord substance is seen to be divided into the central gray and peripheral white matter. The gray matter is composed of ganglion cells and nerve fibers, and the white matter of fibers and their myelin sheaths. The gray matter forms an H-shaped mass, composed of an anterior and posterior horn on each side, united by the gray commissure, in the middle of which lies the central canal. The anterior horns contain ganglion cells, the axons of which enter the anterior roots and form the lower motor neurons. The white matter, consisting of longitudinal bundles of nerve fibers, is regarded as being divided into three columns. The bony spine, provide protection for the spinal cord from excessive movement. Cervical region of spinal cord is more prone for injury because of it is most mobile part.

BLOOD SUPPLY

The spinal cord is richly supplied with blood. There are two posterior spinal arteries, each derived from the corresponding vertebral or posteroinferior cerebellar artery. The single anterior spinal artery is formed by the union of a branch from each vertebral artery. The spinal arteries are reinforced by segmental arteries. The two most important of these are one at C6, and one, the great anterior radicular artery of Adamkiewicz, which usually enters the spinal cord between the T5 and T8 segments. Branches from anterior spinal artery supply the anterior columns and most of the lateral columns. Branches from posterior spinal artery supply the entire posterior columns and the remainder of the lateral columns.

CLINICAL FEATURES OF SPINAL CORD LESIONS

This section discusses the general features of spinal cord lesions and specific findings according to the segmental level of the cord lesion. The signs and symptoms of spinal cord disorders are dependent on the level, longitudinal and transverse extent, and pathological nature of the underlying cause. **Table 1** shows clinical features of spinal cord dysfunction by segmental level location of lesions. **Table 2** shows central cord syndromes, where segments below may be spared. **Table 3** shows how to differentiate intramedullary from extramedullary lesions.

Sensory, motor, and sphincter manifestations are each common and classical features of spinal cord disease, although partial may involve only one or two of these functions. Symptoms include weakness below the level of the lesion, with difficulties

Table 1 Effects of spinal cord dysfunction by segmental level

Location of Lesion*	Possible Effects
At or above C5	Respiratory paralysis Quadriplegia
Between C5 and C6	Paralysis of legs, wrists, and hands Weakness of shoulder abduction and elbow flexion Loss of biceps jerk reflex Loss of brachioradialis deep tendon reflex
Between C6 and C7	Paralysis of legs, wrists, and hands, but shoulder movement and elbow flexion usually possible
Between C7 and C8	Loss of triceps jerk reflex Paralysis of legs and hands
At C8–T1	Horner syndrome (constricted pupil, ptosis, facial anhidrosis) Paralysis of legs
Between T1 and conus medullaris	Paralysis of legs

*Abbreviations refer to vertebrae; the cord is shorter than the spine, so that moving down the spine, cord segments and vertebral levels are increasingly out of alignment. At all levels of cord injury, deep tendon reflexes are altered (initially decreased and later becoming brisk) below the level of the lesion, bowel and bladder control is lost, and sensation is lost below the level of injury.

Table 2 Spinal cord syndromes, their causes, and clinical presentation

Syndrome	Cause	Symptoms and signs
Anterior cord syndrome	Lesions disproportionately affecting the anterior spinal cord, commonly due to infarction (e.g., Caused by occlusion of the anterior spinal artery)	Malfunction of all the tracts except posterior columns, thus sparing position and vibration sensation
Brown-Sequard syndrome	Unilateral spinal cord lesions, typically due to penetrating trauma	Ipsilateral paresis Ipsilateral loss of touch, position, and vibratory sensation Contralateral loss of pain and temperature sensation*
Central cord syndrome affecting the cervical spinal cord	Lesions affecting the center of the cervical spinal cord, mainly central gray matter (including spinothalamic tracts, which cross), commonly due to trauma, syrinx, or tumors in the central spinal cord	Paresis tending to be more severe in the upper extremities than in the lower extremities and sacral regions Loss of pain and temperature sensation in a cape-like distribution over the upper neck, shoulders, and upper trunk, with light touch, position, and vibratory sensation relatively preserved (dissociated sensory loss)
Conus medullaris syndrome	Lesions around L1	Distal leg paresis Perianal and perineal loss of sensation (saddle anesthesia) Urinary retention, frequency, or incontinence Fecal incontinence Hypotonic anal sphincter Abnormal bulbocavernosus and anal wink reflexes
Transverse myelopathy	Lesions affecting all or most tracts of the spinal cord at ≥ 1 segmental level	Deficits in all functions mediated by the spinal cord (because all tracts are affected to some degree)

*Occasionally, only part of one side of the spinal cord malfunctions (partial Brown-Sequard syndrome).

Table 3 Clinical guidelines to differentiate intramedullary and extramedullary tumors

Symptoms/signs	Intramedullary tumors	Extramedullary tumors
Radicular pain	Unusual	Common, may occur early
Vertebral pain	Unusual	Common
Funicular pain	Common	Less common
Upper motor neuron signs	Yes, late	Yes, early
Lower motor signs	Prominent and diffuse	Unusual, if present, segmental distribution
Paresthesia's progression	Descending progression	Ascending
Sphincter abnormalities	Early with caudal lesion (conus cauda equina)	Late
Trophic changes	Common	Unusual

in walking or upper limb function. Sensory symptoms include numbness, tingling, pins and needles, dermal hypersensitivity, burning sensation, altered temperature sensation, and tight band like feelings below the level of lesions. Loss of all voluntary movements and sensation will occur at the level of the lesions, especially when there is spinal cord compression from extrinsic disease involving the vertebral column. The most common sphincter disturbances resulting from spinal cord disease are urgency, frequency, and urge incontinence; less commonly hesitancy or retention occur, except in acute transverse lesions where retention is the rule. Constipation and fecal incontinence occurs, though less often. Other autonomic changes may also be seen, e.g., excessive sweating or vasomotor disturbances below the site of lesion, or Horner syndrome with lesion in the cervical cord.

The clinical signs may be divided into those occurring at the level of the lesion and those due to interruption of long tracts. At the level of a lesion, there may be lower motor neuron signs, with focal muscle wasting, fasciculations, and hypo-or areflexia due to involvement of anterior horn cells. Radicular pain or dermatomal sensory loss may result from damage to sensory roots. The interruption of long tracts will result in upper motor sings below the level of the lesion, with pyramidal pattern of weakness, spasticity, and deep tendon hyper-reflexia with absent abdominal reflexes and extensor plantar responses. Acute severe cord lesions produce a flaccid paraplegia with temporary phase of hypotonia and areflexia before appearance of more characteristic UMN signs.

A complete cord syndrome will result in loss of all sensory modalities below the level of the lesion. Partial syndromes will produce variable findings—posterior column involvement leads to loss of joint position sense, vibration, and two point discrimination, with a positive Romberg's sign and an ataxic gait. Contralateral loss of pain and temperature sensation occurs with lesions involving spinothalamic pathways.

Cauda equina syndrome due to damage to nerve roots at the caudal end of the cord mimics conus medullaris syndrome. It causes distal leg paresis and sensory loss in and around the perineum and anus (saddle anesthesia), as well as bladder, bowel, and pudendal dysfunction. Muscle tone and deep tendon reflexes are decreased in the legs.

DIAGNOSIS

Segmental level neurological deficit suggests spinal cord disorder. Unilateral segmental deficits may result from nerve root or peripheral nerve disorders. Location of a spinal cord lesion can be determined by level and pattern of spinal cord dysfunction. MRI of spine is very useful imaging test for spinal cord lesions. It shows

spinal cord parenchyma, soft tissue lesions, and bone lesions. Plain X-rays are helpful for detection of bone lesions. Myelography is used less often.

MANAGEMENT

The principles of management in children with spinal cord disorders are different from adults. It must be developmentally based and one should consider dynamic changes that occur as a consequence of growth and development.

DISORDERS OF SPINAL CORD

Syringomyelia

It is a fluid-filled cavity within the spinal cord. Some of the predisposing factors are craniocervical junction abnormalities, previous spine injury, and spinal cord tumors. Usually, it results from partial obstruction to CSF flow. At least fifty percent of syringomyelia occurs in children with congenital anomalies (e.g., Chiari malformation, myelomeningocele). It usually begins in the cervical region but extend downward along the entire length of the spinal cord.

Symptoms and Signs

Syringomyelia usually produces central cord syndrome (Table 2). Initially pain and temperature sensory loss occurs. It is usually in a cape-like distribution over the shoulders, arms, and back. It may cause painless burn or cut. It produces weakness, atrophy, fasciculations and hyporeflexia in the upper limbs. Position, vibration sensation and light touch are not affected. Later spasticity in the lower limbs develops. Findings may be asymmetric. MRI of spine with contrast helps in diagnosing syringomyelia and associated anomalies.

Management

Surgical decompression of the foramen magnum and cervical cord is indicated, but it will not reverse severe neurodeficits. Underlying problems are corrected when possible (e.g., anomalies, tumor, etc.)

Craniocervical Junction Abnormalities

Craniocervical junction abnormalities are abnormalities of the occipital bone, foramen magnum, or first two cervical vertebrae. These disorders ranges from asymptomatic problems to devastating neurological problems. The clinical manifestation reflects in the anatomical structures in this region, brainstem, cerebellum, cranial nerves, spinal cord and vertebrae. **Box 1** shows craniovertebral abnormalities and their clinical consequences.

BOX 1 Craniocervical abnormalities and their clinical consequences
• *Fusion of the atlas (C1) and occipital bone:* Spinal cord compression if the anteroposterior diameter of the foramen magnum behind the odontoid process is < 19 mm
• *Basilar invagination (upward bulging of the occipital condyles):* A short neck and compression that can affect the cerebellum, brainstem, lower cranial nerves, and spinal cord
• *Atlantoaxial subluxation or dislocation (displacement of the atlas anteriorly in relation to the axis):* Acute or chronic spinal cord compression
• *Klippel-Feil malformation (fusion of cervical vertebrae):* Deformity and limited motion of the neck but usually no neurologic consequences
• *Platybasia (flattening of the skull-base so that the angle formed by the intersection of the clival and anterior fossa planes is > 135°), seen on lateral skull imaging:* No symptoms or cerebellar or spinal cord deficits or normal-pressure hydrocephalus.

Etiology

Os odontoideum is abnormal bone that replaces odontoid process (**Fig. 1**). Congenital fusion of the atlas and occipital bone is atlas assimilation. *Klippel-Feil anomaly* may be associated with atlanto-occipital anomalies. *Platybasia* may be seen in Chiari malformation. *Achondroplasia* can cause narrow foramen magnum and it may compress the spinal cord. *Atlantoaxial subluxation* or dislocation can be seen in Down syndrome and Morquio syndrome. Although the exact mechanisms of this condition are uncertain, the problem may be related to weakness, laxity of the ligaments and/or abnormalities of bone development. These problems are usually diagnosed between the ages of 6 and 12 years.

Clinical Features

Clinical manifestation can occur spontaneously or after minor neck injury. Presentation depends on degree of compression and structures affected. Common manifestations are headache, neck pain and features of spinal cord compression. Short neck, torticollis, restriction of movements can be seen in some abnormalities (e.g., Klippel-Feil malformation, platybasia, basilar invagination). Sometimes brainstem, cranial nerve and cerebellar deficits can be seen. Vertebrobasilar ischemia can cause intermittent syncope, drop attacks, vertigo, weakness, visual disturbance or altered sensorium.

Diagnosis

MRI of spine detects neural lesions and soft tissue lesions. CT scan shows bone structures and may be done more easily during emergency. Plain X-rays and myelography are sometimes useful.

Treatment

Reduction of craniocervical junction is indicated if lesions are causing neural compression. Head and neck should be immobilized. If reduction is not successful, surgical decompression is indicated. Posterior fixation is indicated if instability persists after decompression.

Tuberculous Spinal Osteitis

Tuberculous spinal infection is still common in less developed regions of the world. The infective process generally begins in the vertebral body and spreads to adjacent bodies, leading their collapse and an angular deformity of the spine (**Figs 2A to C**). It is rare for the deformity as such to be a major factor in compressing

Figure 1 Atlantoaxial dislocation with presence of os odontoideum. Dens is retroflexed and seen causing spinal canal stenosis and cord compression
Figures 2A to C 14-year-old female presented with history of fever, neck pain, and weakness of all four limbs since 15 days. (A) T1 sagittal; (B) T2 sagittal; (C) Postcontrast T1. There is anterior wedge collapse with destruction of the C7 and D1 vertebrae and the intervertebral disc, causing a kyphotic deformity. A large heterogeneous mass is seen in the adjacent anterior epidural space (C7–D4 levels) and the pre- and paravertebral regions (C4–D2 levels). The epidural lesion is seen to severely compromise the spinal canal (diameter of up to 7 mm). The lesion is hyperintense on T2WI and hypointense on T1WI. Evidence of diffusion restriction seen. On the postcontrast scan, the lesion shows peripheral enhancement. Features are suggestive of tuberculosis of spine. There is vertebra plana of the C3 vertebra with an adjacent enhancing mass on left side

the cord, which is more often affected by an extradural tuberculous abscess or tuberculous meningomyelitis. In addition to actual cord compression, which may, however, be absent, interference with the vascular supply of subjacent segments, either by compression of radicular arteries or by endarteritis, is an important factor in producing paraplegia. These conditions probably explain the good outcome that can be achieved by conservative treatment using antituberculous chemotherapy rather than surgical decompression, even in severe cases.

Viral Myelitis

Viral causes of myelitis include poliomyelitis, coxsackie viruses, herpes zoster, herpes simplex, HIV, Epstein-Barr virus, cytomegalovirus (CMV), and HTLV-1. Although number of viruses causes an acute infective myelitis, they may also be associated with a postinfectious myelitis, which is likely not to be the result of viral infection but rather to an immune-mediated response triggered by the viral antigens.

Poliomyelitis and coxsackie viruses produce an acute inflammatory meningomyelitis with cord involvement predominantly affecting the anterior horn cells, leading to patchy, multifocal or sometimes extensive muscle weakness and wasting, with corresponding reflex loss but no sensory abnormality. Varicella zoster usually produces a sensory dermatomal deficit, often with marked pain, due to predominant involvement of the dorsal root ganglion. The associated dermatomal vesicular rash will normally establish the diagnosis.

A transverse myelitis due to viral infections such as those above, although much rarer, may be indistinguishable from a post-infectious transverse myelitis. Such infections are more likely to occur in immunocompromised states, including those with HIV infection. The diagnosis is confirmed by the isolation of portions of viral antigen from the CSF by PCR.

Spinal Cord Injury

Spinal injuries are common at the C1–C2 level in children of 0–3 years old. This is probably due to higher fulcrum of motion in younger children, and weakness of C2 vertebra. Common causes are motor vehicle accidents, falls, recreational or sports activities (e.g., diving accidents and football injuries), and penetration injuries of spine (e.g., knife, gunshot). Violence is common in the age group of 16–20 years. Traumatic birth injury is decreasing. The death due to spinal cord trauma is more common in children compared to adults. **Box 2** shows predisposing conditions to cervical spine injuries.

Major ways of spinal trauma causing spinal cord injury are: forward flexion, lateral flexion, rotation, axial compression, and hyperextension. These forces can result in vertebral distraction, dislocation, fracture, and disc herniation. Bone disruption (fracture or displacement) is the most common cause of spinal cord injury. Spinal cord injury without radiographic abnormality (SCIWORA) is common in children where ligamentous injury causes spinal injury without bone disruption.

Forward flexion injury is seen in children wearing ill-fitting adult types of lap-sash belts (cervical seat-belt syndrome). Axial compression occurs in diving accidents, falls, and sports injuries. Severe hyperextension is seen in the head-shaking injury of child abuse, after neck hyperextension in football games and in infants with C1 to C2 instability.

X-ray of spine may be useful to detect osseous disruption; however it can be normal in 50% of children. CT spine detects subtle spinal fractures. MRI of spine recently replaced CT and myelography as imaging of choice in spinal cord disorders. Stabilization of spine to prevent further injury is important. Intravenous methylprednisolone, bolus of 30 mg/kg followed by infusion at 5.4 mg/kg/hour over next 23 hours can be considered. The benefit is modest at best, and one needs to weigh the risk of potentially serious complications of high dose steroids.

SPINAL CORD TUMORS

Neoplasms of the spinal cord are less common than those found intracranially. The ratio of intracranial/intraspinal neoplasms in children depends on the histology of the tumor. The ratio varies from 20:1 to 5:1. Spinal cord tumors are most commonly found in the thoracic spinal cord followed by location in the cervical, thoracolumbar, and lumbosacral areas. Thus, the divisions having the largest number of segments are areas associated with the highest incidence of tumor.

Types of Tumor

Traditionally, tumors of the spinal canal are divided into extramedullary and intramedullary masses **(Table 4)**.

Extramedullary Tumors

Extramedullary masses erode the bony vertebral column, present asymmetrically, and involve those sensory and motor tracts placed laterally within the substance of the spinal cord parenchyma. Dumbbell lesions, consisting of neurofibromas presenting both inside and outside the neuroforamina, are occasionally encountered.

BOX 2   Predisposing factors for cervical spinal cord injury

- Down syndrome (15% have atlantoaxial instability)
- Klippel-Feil syndrome
- Morquio syndrome
- Larsen syndrome
- Achondroplasia
- Previous spine surgery.

Table 4 Tumors of the spinal cord

Intramedullary	Extramedullary
Astrocytomas • Cystic • Noncystic Ependymomas • Myxopapillary • Well-differentiated Oligodendroglimas	Neurofibromas Dysembryoplastic • Dermoids • Epidermoids • Teratomas • Lipomas Meningiomas Arachnoid cysts Metastatic • Neuroblastoma • Sarcoma • Lymphoma

Reticulum cell sarcomas, lymphomas, neuroblastomas, and other sarcomatous lesions usually present in the context of neoplasms found elsewhere in the body. In the spinal cord, they occur epidurally and present as compressive lesions. Dysembryoplastic lesions are observed in the younger child. The findings of teeth, bones, or calcification on X-ray film suggest a dermoid. These findings may be associated with a sinus tract leading from the surface and extending intraspinally. As with dermoids, tumors usually occur in the lumbosacral midline region, although they may occur anywhere in the spinal column, and may be associated with spina bifida, sacral dimple, port-wine nevus, or excessive clumps of coarse hair. At surgery, the tract extends to the conus. Nerve roots of the cauda equina are often enmeshed in the fatty tumor with varying degrees of neurologic abnormalities. The serpiginous nature of these fatty tumors may make surgery difficult. Despite this problem, with or without surgery, patients often remain relatively stable with little progression of symptoms.

Intramedullary Tumors

Thirty five percent of the pediatric intraspinal tumors are intramedullary. The most intramedullary tumors in children are either astrocytomas or ependymomas. Astrocytomas present as a mass extending over multiple segments of the cord or the entire length of the spinal cord. They may be partially cystic. Because these tumors expand and compress normal tissue, they are more likely to produce slowly progressive signs rather than sudden interruption of neurologic function. Astrocytomas of the spinal cord have hamartomatous features consequently their natural history may be quite prolonged. Gross total resection is the treatment of choice, in the presence of dissemination radiation can provide long-term survivals. In contrast, high grade astrocytomas of the spinal cord have a poor prognosis with median survival of 12 months.

Ependymomas are less common than astrocytomas. These are classified into two types: well differentiated cellular or well-differentiated myxopapillary tumors. Treatment consists of laminectomy with decompression and attempt at complete removal. Complete removal is the treatment of choice, resulting in cure. Radiation can be considered if tumor not resected completely. In general, the prognosis for ependymomas of the spinal cord is better than for astrocytoma, with 5-year survival rates of 72–100%.

Clinical Characteristics

Signs and symptoms of spinal cord neoplasms can be insidious and misleading. History is often vague, and early in the course of the disease there may be a paucity of clinical signs. Common complaints are extremity weakness, abnormalities of gait, or pain in the extremities, back, or even periumbilical region. Unfortunately, consideration of a spinal cord mass may not enter the differential diagnosis until there is considerable progression or a spinal cord sensory level becomes obvious. In young children, because enuresis is common, a history of changing patterns of continence may not be elicited. In the very young, who are not bowel or bladder trained, sphincter abnormalities may be over-looked. A clue to the presence of neurogenic bladder is incontinence of urine associated with crying or straining at stool. Loss of rectal tone is a common finding in patients with spinal cord tumors.

Changes in posture, nonspecific complaints of back pain, or even unexplained abdominal pain may by associated with disease of the spinal cord. Pain is more often dull aching, burning, and diffuse, rather than sharp. Sharp pain is uncommon. Classic signs of a sensory level with or without a Brown-Sequard syndrome are rarely encountered.

Any pain accentuated by either Valsalva maneuvers, such as sneezing, coughing, or straining at stool, or by straight leg rising should be evaluated. These maneuvers, by stretching the meninges, may cause root irritation in a patient with compressive disease of the spinal canal.

Subtle physical findings may be mild scoliosis, discrepancy in foot or leg length, or vasomotor changes in the lower extremities. Findings are hyper-reflexia, clonus, and Babinski responses suggest disease of the corticospinal tracts. Proprioceptive, vibratory loss, or a sensory level, no matter how subtle, should raise suspicion of intraspinal pathology.

Diagnostic Studies

X-ray spine—an increase in the interpedicular distance may suggest a long standing intramedullary process. Destructive changes of bone are more frequently associated with metastatic disease. Distortion or widening of the neuroforamina may be observed with extramedullary tumors, such as neurofibromas or metastatic disease to the spinal canal. With slowly growing intraspinal tumors, the changing forces of an asymmetrical spinal lesion may alter vertebral growth in such a manner as to cause scoliosis. Bony abnormalities may be associated with a paravertebral soft tissue mass.

Diagnosis is confirmed by neuroimaging. MRI can visualize the entire length of the cord in the sagittal diameter. By this method, intramedullary masses can be readily separated from extramedullary lesions. Further, unlike myelography, MRI readily identifies intramedullary cysts. **Figures 3A to D** shows osteochondroma at C2 vertebra causing spinal cord compression.
Figures 3A and B Osteochondroma at C2 vertebra. 11-year-old girl presented with neck pain and quadriparesis. Mid sagittal and parasagittal T2 MR images of the cervical spine demonstrate osteochondroma arising from the right C2 lamina causing severe spinal canal narrowing with compressing the spinal cord and spinal cord signal changes
Figures 3C and D Axial T1 and T2 MR images of the cervical spine demonstrate osteochondroma arising from the right C2 lamina causing severe spinal canal narrowing with compressing the spinal cord and spinal cord signal changes

Management

Surgery

In all cases, regardless of etiology and extent of defects, surgical decompression is recommended. The spinal cord is resilient. In general, recovery depends on the length and duration of symptoms. Any evidence of compression of long tract motor or sensory function through the spinal cord limits hope for recovery.

Adjuvant Management

Radiation is recommended for subtotally resected spinal cord tumors: however, even this approach is not without controversy. Many suggest radiation of all subtotally resected intramedullary tumors, regardless of histology. Recommended radiation doses to the lesion range between 2500 cGy and 5000 cGy in 180–200 cGy fractions with a margin of 2–3 cm.

Chemotherapy

There is lack of data on use of chemotherapy in low grade astrocytomas of the spinal cord. Most commonly, varying combinations of carboplatin and vincristine have been used.

Complications

The main complications after treatment of spinal cord tumors are orthopedic. Radiation-associated arachnoiditis or myelopathy also contributes to orthopedic abnormalities. Non-neurologic complications are kyphoscoliosis and, after radiation, limited growth of the vertebral column. Neurologic complication after surgical treatment may be flaccid or spastic paraplegia or quadriplegia and bowel or bladder incontinence. Decubitus ulcers, pathologic fractures, and dislocated hips may occur because of loss of trophic neurologic input. Although treatment may be curative, morbidity can be significant. Skilled and continuous rehabilitative care is necessary to improve the quality of life.

Prognosis

Prognosis for spinal cord tumors is much better than that for the child with an intracranial tumor. Surgical intervention may delay

the growth and progression of these tumors. In the more aggressive tumors surgery coupled with judicious use of radiotherapy has been associated with long-term survival or cure. Unfortunately, morbidity is quite significant. The insidious nature of spinal cord tumors, their relative rarity, and their lack of clinical specificity continue to challenge the most astute neurologic clinicians.

IN A NUTSHELL

1. Rapid evacuation and treatment prevents permanent severe neurologic disability.
2. MRI is the imaging of choice for spinal cord disorders.
3. Spinal dermoid can cause recurrent meningitis.
4. Good outcome can be achieved by conservative treatment using antituberculous chemotherapy for tuberculosis of spine.
5. Spinal cord injury without radiographic abnormality (SCIWORA) is ligamentous injury causing spinal cord injury without bone disruption is common in children.
6. The surgical treatment of spinal disorders in children must take into account the expected growth and development of the spine.

Chapter 42.28
Pseudotumor Cerebri
Anaita Udwadia-Hegde, Omkar P Hajirnis

Pseudotumor cerebri (also known as benign intracranial hypertension or primary idiopathic intracranial hypertension) is a clinical syndrome with raised intracranial pressure in the absence of space-occupying lesion or apparent obstruction to the CSF pathways. This increased intracranial pressure is marked at more than 200 mm in infants and more than 250 mm in children. Papilledema is universally present in older children whose fontanel is closed. To some extent it is a diagnosis of exclusion, dependent on excluding identifiable causes of raised intracranial pressure. It can be *primary* or *secondary*. The main causes of pseudotumor cerebri are listed in **Table 1**.

CLINICAL FEATURES AND DIAGNOSIS

Headache is the most common feature and often the sole presenting complaint. This is made worse by maneuvers that raise the intracranial pressure, such as coughing and bending. Transient visual impairment and diplopia (secondary to VI cranial nerve palsy) may also be seen. Most patients though are alert and lack constitutional symptoms. Infants may manifest with irritability, the sunset sign, and a bulging anterior fontanel. Papilledema (occasionally with hemorrhages) or at least some degree of blurring of the disc margins is the hallmark of the disease. Most often the papilledema is bilateral, although it can be asymmetric or unilateral. An MRI with a venogram is useful to rule out dural venous sinus thrombosis. The investigations which need to be performed in a patient with pseudotumor cerebri are detailed in **Box 1**. Visual loss is the main concern and complication (questioning the term *benign* attached to this variant of raised intracranial tension). Sequential perimetry and assessments of visual acuity are advised. Diagnostic criteria for pseudotumor cerebri are shown in **Box 2**.

TREATMENT

Treatment includes elimination of contributory factors like weight, drugs and diet and treatment of the underlying cause. The initial lumbar puncture is both diagnostic and can be therapeutic to release the raised intracranial pressure. Serial lumbar punctures are then done every 5–7 days, with drainage of 20–25 mL of CSF on each tap to lower the closing pressure below 200 or 250 mm Hg in infants and children, respectively. Acetazolamide (10–30 mg/kg/day in two divided doses) or diuretics like furosemide (1 mg/kg/day in two divided doses) decrease the formation of CSF and are used in children with unimpaired visual function. Topiramate and steroids are other pharmacological therapies found to be useful.

The main indications for surgical intervention are deterioration in vision and severe incapacitating headaches despite aggressive medical management. An optic nerve sheath fenestration and CSF diversion (usually, lumboperitoneal shunting) are modalities out of which the former one is usually preferred.

Optic nerve sheath fenestration involves cutting slits or rectangular patches in the dura surrounding the optic nerve immediately behind the globe allowing direct drainage of CSF into the orbital fat, where it is absorbed into the venous circulation. The fenestration besides lowering the optic nerve edema and restoring visual function also acts as a safety valve and keeps the pressure from being transmitted to the optic nerve. However, besides complications of diplopia and optic nerve injury in one-third of cases secondary visual decline may occur in a few years necessitating a repeat surgery or alternative treatment.

Table 1 Etiology and classification of pseudotumor cerebri

Primary pseudotumor cerebri No recognized cause (Idiopathic pseudotumor cerebri)		
Secondary pseudotumor cerebri		
Drugs	*Systemic disorders*	*Metabolic disorders*

• Use of corticosteroids or corticosteroid withdrawal
• Hypervitaminosis A
• Tetracyclines or minocycline
• Nalidixic acid
• Phenothiazines
• Sulfonamides
• Oral contraceptives
• Phenytoin
• Cyclosporine
• Cytarabine
	I. Secondary to neurological disorders
	  • Dural venous sinus thrombosis (associated with otitis media, mastoiditis, or head trauma)
	  • Altered CSF composition (meningitis)
	  • Arteriovenous malformation draining into a venous sinus (Dural arteriovenous fistula)
	  • Guillain-Barré syndrome
	
	II. Secondary to systemic disorders
	  • Hypovitaminosis A
	  • Systemic lupus erythematous
	  • Behçet disease
	  • Antiphospholipid syndrome
	  • Familial deficiency of antithrombin III
	  • Severe anemia (aplastic or iron deficiency, Wiskott-Aldrich syndrome)
	  • Nephrotic syndrome
	  • Leukemia
	  • Non-Hodgkin lymphoma
	  • Turner syndrome
	  • Crohn disease
		• Obesity
		• Refeeding of malnourished children

		• Pregnancy
		• Hypoparathyroidism
		• Hyperparathyroidism
		• Hyperthyroidism
		• Thyroxine replacement
		• Hyperadrenalism
		• Addison disease
		• Vitamin D-dependent rickets
		• Hypophosphatasia

BOX 1 Investigations in a patient suspected with pseudotumor cerebri

- *Hematological investigations* for ruling out metabolic and systemic disorders:
  - Complete blood count and erythrocyte sedimentation rate
  - Autoimmune disorder profile (ANA profile, e.g., anti-dsDNA and anti-ssDNA)
  - Prothrombotic profile (e.g., Protein S, Protein C, homocysteine levels, antithrombin III, factor V Leiden variant, antiphospholipid/anticardiolipin antibodies, lupus anticoagulant, and platelet aggregation studies to name a few)
- *CSF examination* including the opening pressure which is vital for diagnosis along with routine glucose, cell count and protein examinations. However, it should always be kept in mind that brain imaging should be obtained before a lumbar puncture is performed
- *Neuroimaging*
  - Magnetic resonance imaging (MRI) of the brain with magnetic resonance venography (MRV) is preferred to enable one to exclude thrombosis of a major venous sinus.
  - Ultrasonography has been used to measure the diameter of the optic nerve sheath.
- *Optic nerve function* should be carefully monitored with an assessment of visual acuity, color vision, optic nerve head appearance, and perimetry.

BOX 2 Modified Dandy criteria for pseudotumor cerebri

1. Signs and symptoms of increased intracranial pressure
2. No localizing neurological signs except for unilateral or bilateral VI cranial nerve palsy
3. Increased cerebral spinal fluid opening pressure but otherwise normal cytologic and chemistry values
4. Normal symmetric ventricles must be demonstrated by neurological imaging.

IN A NUTSHELL

1. Pseudotumor cerebri is a clinical syndrome with raised intracranial pressure in the absence of space-occupying lesion or apparent obstruction to the CSF pathways.
2. It may occur secondary to many drugs, neurological or systemic illnesses, and certain endocrine/metabolic derangements.
3. Bulging anterior fontanel and headache are the main presentations in infants, and children, respectively.
4. Visual loss is the main concern and complication necessitating therapy.
5. Treating the underlying cause, serial lumbar punctures, acetazolamide, are fenestration of optic sheath, are the few treatment modalities.

Section 43 NEUROMUSCULAR DISORDERS

Section Editors *Sheffali Gulati, J Andoni Urtizberea*

Chapter 43.1
Approach to Diagnosis of Neuromuscular Disorders

*Sheffali Gulati, Jaya Shankar Kaushik,
J Andoni Urtizberea, MC Sharma*

Neuromuscular disorder constitutes a broad category of diseases that impair the function of skeletal muscles. Neuromuscular disorders constitute a significant proportion of pediatric neurological diseases. Broadly it is classified based on neuroanatomical site of lesion into anterior horn cell disease, neuropathy, disorders of neuromuscular junction and myopathy **(Fig. 1)**. It could result from either a genetic defect in structure of muscle (congenital myopathy and muscular dystrophy) or acquired defect (dermatomyositis) **(Flow chart 1)**.

Common clinical presentations in pediatric neuromuscular (NM) diseases include floppy infant and difficulty in walking. Floppy infant presentation may vary from subtle delay in attainment of motor milestones to severe manifestations like respiratory distress with or without diaphragmatic weakness, feeding difficulty and hypotonia. On other hand, older children with neuromuscular weakness may present with difficulty in walking, abnormal gait, enlargement of muscles or pain in muscles or recurrent chest infection. Other clinical presentations of neuromuscular disorders include effort intolerance, easy fatigability and acute rhabdomyolysis.

Weakness refers to loss of muscle strength. In common parlance, it needs to be differentiated from fatigue and asthenia which are common among those with systemic illness. Fatigue refers to inability to perform the task repeatedly, resulting from lack of energy. Similarly, the term asthenia is used for exhaustion without any neuromuscular weakness. Pediatric NM disease may present with involvement of specific group of muscles like facial, bulbar, respiratory, neck muscles, proximal or distal appendicular muscles. Precise neuroanatomical localization is essential for basic approach to clinical thinking and laboratory approach.

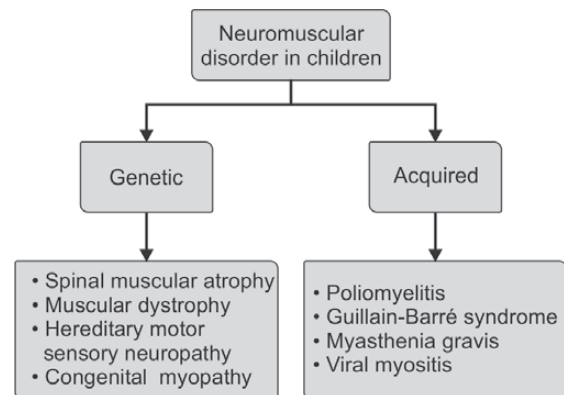
Flow chart 1 Broad classification of pediatric neuromuscular disorders based on etiology


Figure 1 Schematic approach to site of lesion (neuroanatomical localization) in pediatric neuromuscular disorders

NEUROANATOMICAL LOCALIZATION

Precise diagnosis of neuromuscular disorder requires thorough history, focused examination and thoughtful choice of correct investigation. Accurate localization in nervous system is the key approach to neuromuscular disorders. Neuromuscular disorders result from a defect in motor unit comprised of anterior horn cells, axons, nerve, neuromuscular junction and muscle fiber.

Presence of generalized weakness with absent deep tendon reflexes (DTR), with presence of tongue fasciculation points to anterior horn cell pathology. Most of plexopathy or neuropathy will have distal muscle weakness, diminished DTR with or without sensory involvement. In contrast, disorders of neuromuscular junction manifest with ptosis, restriction of extraocular movements, and possibly proximal girdle weakness with normal DTR. Presence of symmetrical proximal girdle weakness with normal or diminished DTR points to myopathy **(Table 1)**. Neuromuscular weakness that results from upper motor neuron disease will manifest with hypertonia, brisk DTR, extensor plantar response and weakness involving antigravity muscles with flexors of lower limb and extensors of upper limb. Clinical symptoms vary according to site of involvement [central nervous system (CNS), anterior horn cell, nerve, neuromuscular junction or muscle].

Clinical Correlate: Neuroanatomical Localization

Floppiness or hypotonia in an infant could result from either a defect in CNS or defect in motor unit. Presence of hypotonia out of proportion to weakness along with normal or brisk DTR and extensor plantar response indicates central cause of floppiness. Similarly, presence of seizures, cognitive impairment and dysmorphism favors central cause. In contrast, presence of weakness, hypotonia, hyporeflexia or areflexia with flexor plantar response indicates motor unit dysfunction. In general, floppy but strong baby has CNS pathology whereas floppy and weak baby has motor unit pathology. Presence of areflexia with tongue fasciculation indicates anterior horn cell involvement (neuronopathy).

In general, proximal weakness is an indicator of myopathy (except congenital myotonic dystrophy) whereas distal weakness goes in favor of neuropathy [exception is spinal muscular atrophy (SMA) type III]. Most of myopathies have symmetrical weakness. Wasting of muscle could result from long-standing myopathy or secondary to neuropathy. Muscular hypertrophy could result from wide range of neuromuscular disorders like Duchenne muscular dystrophy (DMD), Becker muscular dystrophy (BMD), myotonia congenita, or SMA type III, or cysticercosis. Presence of fasciculations is an indicator for involvement of anterior horn cells classically seen in SMA.

Table 1 Localization of neuromuscular weakness

Clinical features	Anterior horn cell	Nerve	Neuromuscular junction	Muscle
Weakness	P = D	D > P	P = D	P > D
Muscle atrophy	Yes	Yes	No	Late stages
Tone	Decreased	Decreased	Decreased	Decreased
DTR	Absent	Absent or diminished	Normal or diminished	Normal or diminished
Plantar response	Mute or flexor	Flexor	Flexor	Flexor
Sensation	Normal	Diminished	Normal	Normal

Abbreviations: P, proximal; D, distal.

Disorders of neuromuscular transmission cause fatigable weakness with predilection for cranial and proximal muscles. In children with plexopathy like brachial plexus injury, both proximal and distal muscles are involved with diminished sensation and DTR. Presence of sensory loss, distal atrophy resulting in stork like legs with absent DTR and foot deformities like hammer toe are hallmark for hereditary neuropathies like hereditary motor sensory neuropathy.

Clinical Approach by History

Eliciting an appropriate history gives major clue to diagnosis of underlying neuromuscular disorder. History should address following points: age at onset, whether the illness is progressive or static, is it confined to neuromuscular alone or whether CNS is also involved.

Birth history History begins from antenatal history of decreased fetal movement or polyhydramnios which indicates congenital onset of neuromuscular weakness as seen in congenital myopathy or congenital myotonic dystrophy. Birth history of weak cry at birth, history of being floppy, feeding difficulty, respiratory distress with prolonged ventilatory support and difficulty in weaning in neonatal period are pointers of neuromuscular disease. Other points to elicit in birth history include breech presentation, presence of congenital dislocation of hip and early contractures.

Developmental history Developmental domains should be assessed in all four domains: (1) gross motor, (2) fine motor, (3) cognitive domain and (4) language domain. Presence of developmental dissociation with isolated motor delay with preserved cognition and language again favors neuromuscular disorder. Coexistence of cognitive delay, language/speech delay, vision, hearing impairment or presence of seizure is an indicator towards CNS involvement. It is not uncommon to have muscular disease along with CNS involvement as in DMD, alpha dystroglycanopathies [including Fukuyama congenital muscular dystrophy (CMD), myotonic dystrophy and mitochondrial disease.

Presenting complaints Broadly, neuromuscular complaints could be divided into negative symptoms (weakness, fatigue, exercise intolerance, muscle atrophy) and positive symptoms (myalgia, cramps, contractures, myotonia, myoglobinuria, pain and paresthesia). History of abnormal gait, frequent falls, difficulty in getting up from the floor and difficulty in climbing stairs point towards muscular dystrophy. Pain is uncommon in most of pediatric neuromuscular disorder except in dermatomyositis and polyradiculoneuropathy. Muscle cramps and muscle stiffness are nonspecific complaints, unless when precipitated by exercise and associated with myoglobinuria.

Family history History of consanguinity should be enquired and a three generation pedigree should be made to look for inheritance pattern **(Table 2)**. In the family history, enquire if any of family members use wheelchair, has spinal or skeletal deformity or has any functional limitations. History of early deaths and familial cardiac disease should also be elicited.

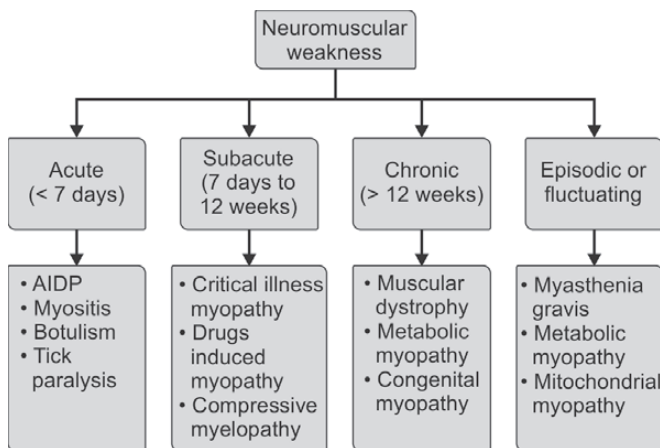
Age at onset Neuromuscular weakness which manifest at birth and early neonatal period include SMA, congenital myotonic dystrophy, congenital myopathy, CMD, congenital myasthenic syndrome, glycogen storage disease and carnitine deficiency. Whereas, other muscular dystrophies, inflammatory myopathy, metabolic myopathy could manifest in early childhood.

Onset of weakness Neuromuscular weakness could be acute, subacute or insidious in onset **(Flow chart 2)**. Acute onset of generalized neuromuscular weakness could include acute inflammatory polyradiculoneuropathy, acute infectious myositis or secondary to neuromuscular blockade as in botulism and

Table 2 Inheritance pattern in neuromuscular disorders

Inheritance pattern in neuromuscular disorders	
Autosomal dominant	FSHD, LGMD, OPMD, myotonic dystrophy
Autosomal recessive	LGMD and metabolic myopathy
Maternal transmission	Mitochondrial myopathy
X-linked recessive	Duchenne, Becker and EDMD

Abbreviations: FSHD, facioscapulohumeral muscular dystrophy; LGMD, limb-girdle muscular dystrophy; OPMD, oculopharyngeal muscular dystrophy; EDMD, Emery-Dreifuss muscular dystrophy.

Flow chart 2 Classification of neuromuscular disorders based on temporal pattern of evolution


tick paralysis. Weakness secondary to drugs (steroid induced myopathy) and prolonged intensive care unit stay (critical illness myopathy) could be subacute in onset. Most of other neuromuscular illness including muscular dystrophy, endocrinal (hypothyroid) myopathy and metabolic myopathy have insidious onset.

Any neuromuscular weakness with acute or subacute progression indicates underlying systemic illness or when associated with muscle pain could suggest inflammatory myopathy like dermatomyositis. Fluctuating weakness with waxing and waning course is highly suggestive of mitochondrial myopathy, myasthenia and inflammatory myopathy like juvenile dermatomyositis. Episodic weakness with complete recovery strongly suggests metabolic myopathy (glycolytic enzyme defects) or ion channel disturbance (channelopathies like periodic hypokalemic paralysis) or myasthenia.

Progression of weakness Progression of weakness could be slowly progressive or rapidly progressive or may have fluctuating or episodic course. Most of neuromuscular disorders including muscular dystrophy and neuronopathies like SMA have slow progression. Most of neonatal onset weakness including congenital myopathy, congenital myotonic dystrophy and congenital myasthenia are nonprogressive with gradual improvement in the functional ability with appropriate intervention. Disease progression is often superimposed by normal development; as a result parents report stabilization or rather improved function even among children with progressive muscular dystrophy. Moreover, seasonal improvement is often noted with outdoor activity, rather outdoor activity including water sports are known to improve the neuromuscular function.

Extent of involvement Weakness in children could manifest with frequent falls, tripping over floor, stamping gait and difficulty in walking suggestive of distal lower limb weakness. They could present with difficulty in getting up from floor or from toilet or low lying chair (hip flexor weakness) and walking upstairs (hip extensor weakness) and downstairs (quadriceps weakness) suggestive of proximal lower limb weakness. The upper limb weakness could present with inability to lift the arm (proximal shoulder girdle weakness) or inability to hold the objects, poor hand grip, poor handwriting and inability to button and unbutton shirt (distal).

Weakness could also manifest with inability to lift head off the bed while attempting to get up from lying down position (neck flexor weakness), inability to sit up from lying down position (truncal weakness), drooping of eyelids (ptosis), diplopia (extraocular muscle weakness), and difficulty in deglutition or nasal regurgitation of feeds (bulbar weakness). Dull facial expression, wasting of temporalis muscle, failure to close the eyes completely, inability to purse the lips, inability to clear food particle caught between lips and gums, inability to suck from a straw or blow balloons is marker towards facial weakness. Presence of slurred speech with difficulty in pronouncing words *d, n, l* and *t* points to tongue muscle weakness. Presence of respiratory distress with paradoxical breathing and dyspnea indicate diaphragmatic weakness. Truncal weakness will manifest with inability to get up from lying down position and prolonged immobilization leads to scoliosis. History of diurnal variation, rapid fluctuation of weakness with febrile illness is pointer towards myasthenia and other neuromuscular junction abnormalities. **Figure 2** summarizes the extent of neuromuscular involvement.

Other presenting features History of muscular pain is common among children with inflammatory myopathy like dermatomyositis or polymyositis or acute infective viral or bacterial myositis. Adolescent female presenting with limb-girdle weakness and pain with presence of violaceous discoloration of eyelid and punctate ulceration in extensor surface of limbs is hallmark presentation of juvenile dermatomyositis. History for presence of rash, joint pain should be elicited to look for connective tissue disorders. Medication history should be carefully elicited **(Table 3)**.

Postexertional pain or muscular cramps with or without history of myoglobinuria (passage of red-colored urine) is an indicator towards metabolic myopathy. Exaggeration of muscle stiffness with cold is known with paramyotonia congenita. Presence of diurnal variation, worsening with febrile illness, prominent extraocular symptoms and ptosis is a marker towards myasthenia gravis. History of excessive sweating, breathlessness, orthopnea in a child with suspected neuromuscular weakness could suggest cardiomyopathy.

Precipitating factors Weakness precipitated with fever or fasting is suggestive of fatty acid oxidation disorder. The rapid onset of neuromuscular weakness in a previously healthy adolescent precipitated by high carbohydrate meal like following a heavy dinner is pointer towards hypokalemic periodic paralysis. Pain, weakness and passage of red urine (myoglobinuria) following an exercise could lead to possibilities of metabolic myopathy (glycolytic enzyme defect like McArdle disease or myophosphorylase deficiency) or mitochondrial disorders or lipid storage myopathy.

Pattern of weakness There are roughly six patterns of weakness in pediatric neuromuscular diseases **(Table 4)**. Limb-girdle weakness involves proximal muscles of upper and lower limb, along with neck extensor weakness. Majority of neuromuscular disease have this pattern of weakness. Distal weakness is often associated with
Figure 2 Extent of neuromuscular involvement

Table 3 Common drugs implicated in neuromuscular diseases in children

Myopathy	Neuropathy	Both
Corticosteroids	Cisplatin	Amiodarone
Cyclosporine	Isoniazid	Chloroquine
D-penicillamine	Metronidazole	
Zidovudine	Phenytoin	
	Pyridoxine	
	Vincristine	

distal atrophy more common with neuropathy and few distal myopathies **(Table 4)**. Scapuloperoneal muscle weakness refers to involvement of parascapular muscles of proximal arm and anterior compartment of leg. Other patterns are fairly specific for certain neuromuscular disease as outlined in **Table 4**. **Figures 3A to D** depicts the pattern of weakness in muscular dystrophy.

Associated systemic involvement One should look for associated systemic complications including cardiac involvement as seen in DMD, BMD, Emery-Dreiffuss muscular dystrophy and acid maltase deficiency. Respiratory muscle (intercostal and/or diaphragmatic) weakness is seen among children with congenital myopathies, CMD, spinal muscular atrophy and more rarely in mitochondrial disorders, congenital or inflammatory myopathy. Hepatic involvement is observed among mitochondrial disorders, acid maltase deficiency, debranching enzyme deficiency and carnitine deficiency. Presence of facial dysmorphism could suggest congenital myopathy. Ocular involvement is common in congenital myotonic dystrophy, CMD and mitochondrial disorder.

Examination

Vitals One should look for clinical evidence of tachycardia, tachypnea and respiratory distress with paradoxical breathing which may point to diaphragmatic weakness. Presence of features of congestive heart failure in a child with neuromuscular weakness could be an indicator of underlying cardiomyopathy. Recording baseline blood pressure is essential before starting corticosteroid therapy in children with DMD.

Anthropometry Children with inherited neuromuscular diseases often have wasting of muscles leading to chronic malnutrition. At the same time, children with dystrophy who become nonambulatory have a tendency to gain weight. Monitoring anthropometric parameters is essential for appropriate intervention.

General physical examination Presence of heliotrope rash over eyelids along with Gottron papules in the knuckles in a child with progressive painful proximal myopathy is suggestive of dermatomyositis **(Figs 4A and B)**. Clinical features of facial dysmorphism or neurocutaneous markers could suggest a co-existing CNS involvement. Respiratory involvement can be assessed bedside by asking the child to count to 50 in a single breath (single breath count test).

Neurological examination Intelligence and cognitive ability needs assessment. Gait and posture needs to be assessed by asking the patient to stand with feet closed, standing and walking on heels and toes, rising from low chair or squatting posture without using arms and rising from supine to sitting without arm. These maneuvers will elicit soft neurological weakness which might often be missed with routine neurological examination.

Table 4 Patterns of neuromuscular weakness in children

Pattern of weakness	Differentials
Progressive proximal limb-girdle weakness	• Muscular dystrophy (Bethlem myopathy, dystrophinopathy, FSHD) • Inflammatory myopathy (dermatomyositis, polymyositis) • Juvenile spinal muscular atrophy • Metabolic myopathy (acid maltase def, carnitine def, debrancher enzyme def, mitochondrial myopathy) • Endocrine myopathy
Progressive distal limb weakness	• *Congenital myopathy:* Nemaline rod, central core, centronuclear myopathy • Muscular dystrophy (EDMD, FSHD) • Neuropathy (CMT, giant axonal neuropathy, drug induced, systemic vasculitis) • Distal myopathy (myotonic dystrophy)
Scapuloperoneal weakness	• Scapuloperoneal dystrophy • Emery-Dreifuss dystrophy • LGMD 1B (laminopathy) • LGMD 2A (calpainopathy) • LGMD 2C-F (sarcoglycanopathies) • LGMD 2I (FKRP)
Ptosis	Myasthenia gravis, centronuclear and nemaline rod myopathy, myotonic dystrophy
Ptosis and ophthalmoplegia	Progressive external ophthalmoplegia, oculopharyngeal muscular dystrophy, myasthenia gravis, Lambert-Eaton syndrome
Prominent neck extensor weakness	• Dermatomyositis • Polymyositis • Facioscapulohumeral dystrophy • Myotonic dystrophy types 1 and 2

Abbreviations: FSHD, facioscapulohumeral dystrophy; EDMD, Emery-Dreifuss muscular dystrophy; CMT, Charcot-Marie-Tooth; LGMD, limb-girdle muscular dystrophy; FKRP, Fukutin-related protein gene; def, deficiency.
Figures 3A to D Patterns of weakness in muscular dystrophy. (A and C) Proximal limb-girdle weakness seen among DMD and LGMD; (B) Scapuloperoneal weakness seen among EDMD and (D) Facioscapulohumeral weakness seen in FSHD
Figures 4A and B Periorbital heliotrope rash (A) and Gottron papule (B) along the knuckles of hands in a child with juvenile dermatomyositis

- Look for gait (ambulatory) and posture (nonambulatory):
  – Waddling gait with proximal myopathy like DMD (Gowers' sign)
  – Waddling gait and lordotic posture is suggestive of proximal hip girdle weakness observed among children with muscular dystrophy
  – Stamping gait (or weakness of foot dorsiflexor) is common among peripheral neuropathy
  – Toe walking is an indicator of muscular dystrophy, spinal dysraphism, spastic diplegia or a normal variant. It can be secondary to early ankle contractures as seen in children with calpainopathy **(Fig. 5)**.
  – Lordotic posture is a marker of proximal girdle weakness
  – Gowers' sign is an indicator of proximal hip girdle weakness **(Figs 6A to D)**.
- *Look for active and passive tone* Hypotonia with areflexia is a pointer towards involvement of motor unit (myopathy, neuropathy, NM disorders) whereas hypotonia with brisk reflexes is pointer towards CNS etiology. Look for features of myotonia in child and parents (congenital myotonic dystrophy).
- *Look for clinical features in face* Asymmetric/Oblique smile [facioscapulohumeral muscular dystrophy (FSHD)] **(Fig. 7)**, ptosis (myasthenia gravis), ophthalmoplegia [Kearns-Sayre syndrome, chronic progressive external ophthalmoplegia (CPEO)] and myotonia of eyelid (myotonia congenita).
- *Clinical features in upper limb and trunk* Neck flexor weakness (DMD), paraspinal contractures (rigid spine syndrome),

winged scapula (FSHD), contractures of elbow (Emery-Dreifuss muscular dystrophy) and hyperextensibility of distal joints as seen in Ullrich variant of CMD **(Fig. 8)**. Winging of scapula is demonstrated in **Figure 9**.

- *Clinical features in lower limb* Inverted Champagne bottle (peroneal muscular atrophy), hypertrophy of extensor digitorum brevis (EDB) (DMD) **(Fig. 10)**, pes cavus (Friedreich's ataxia) and talipes equinovarus (DMD). Pes cavus deformity is demonstrated in **Figure 11**.
- Examine the mother for evidence of myotonia (ask her to close her fist and then open it suddenly) and features of myasthenia (ptosis, weakness).
- Look for wasting of muscles including sternocleiodomastoid muscle, trapezius muscle, winging of scapula and atrophy of intrinsic muscles of hands.
- Look for exaggerated lumbar lordosis. Wasting of quadriceps muscle, anterior compartment of legs, tapering of legs distally, tightness of heel cords, pes cavus, pes planus and presence of foot drop **(Fig. 11)**.
- Look for retinopathy, deafness, cardiac dysfunction, respiratory insufficiency, visceral enlargement and any other clue susceptible to guide the clinician's assessment.

Analysis of the case at the end of history and examination is briefly summarized in **Table 5**. An algorithm suggested for analysis of muscle disease is outlined in **Flow chart 3**.

LABORATORY INVESTIGATIONS

Basic laboratory approach to neuromuscular disorders is outlined in **Flow chart 4**. **Flow chart 5** depicts the approach to a child with progressive symmetrical proximal muscle weakness (DMD phenotype). Over all laboratory investigations essential for diagnosis of neuromuscular disorders are as follows:

Preliminary Investigations

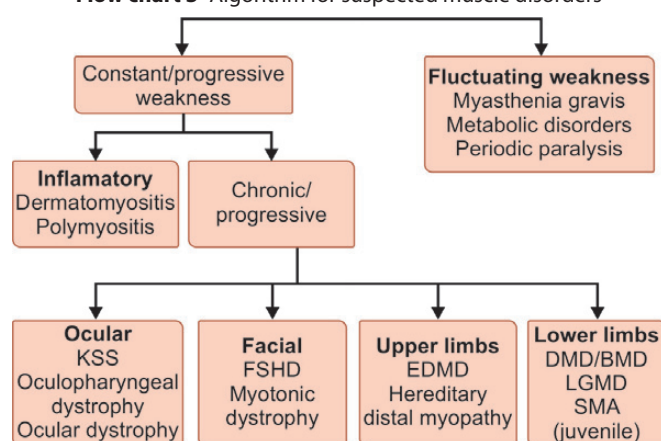
Preliminary investigations including routine hematological and biochemical investigations may give certain clue to neuromuscular disease. For example, presence of raised erythrocyte sedimentation rate (ESR), C-reactive protein (CRP) and total leukocyte count (TLC) might indicate dermatomyositis. Electrolyte abnormalities especially hypokalemia and hyperkalemia are associated with periodic paralysis. Raised serum creatinine phosphate kinase (CPK), urine myoglobinuria, hyperkalemia, raised aldolase, lactate dehydrogenase (LDH) and aspartate aminotransferase [serum glutamate-pyruvate transaminase (SGPT)] could indicate rhabdomyolysis or simply muscular dystrophy.

Specific Clinical Tests

In children with suspected myasthenia with equivocal repetitive nerve stimulation test (RNST) findings, neostigmine challenge test can be performed. In this test, subcutaneous (SC) injection of

Table 5 Analysis and summary of clinical findings based on history and examination

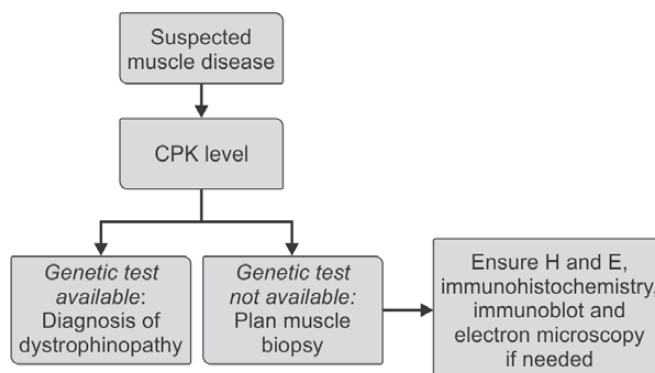
Analysis based on history and examination
1. *Age at onset*: Neonatal, infantile, early childhood, school aged or adolescent
2. Proximal weakness or distal weakness
3. *Extent of weakness*: Look for involvement of arms, legs, trunk, neck flexor, neck extensor, extraocular muscle, ptosis, bulbar muscles and respiratory system weakness
4. *Progression of weakness*: Nonprogressive versus progressive weakness; if progressive whether rapid or slow progressive
5. *Current functional status*: Based on GMFM classification
6. *Inheritance pattern*: Autosomal dominant, autosomal recessive, X-linked dominant or X-linked recessive inheritance

Flow chart 3 Algorithm for suspected muscle disorders


Abbreviations: KSS, Kearns-Sayre syndrome; FSHD, facioscapulohumeral muscular dystrophy; EDMD, Emery-Dreifuss muscular dystrophy; DMD, Duchenne muscular dystrophy; BMD, Becker muscular dystrophy; LGMD, limb-girdle muscular dystrophy; SMA, spinal muscular atrophy; dys, dystrophy.

neostigmine is administered under strict ECG and vital monitoring to look to objective improvement in ptosis (measured by scale with serial photographs for 15 min every 3 min).

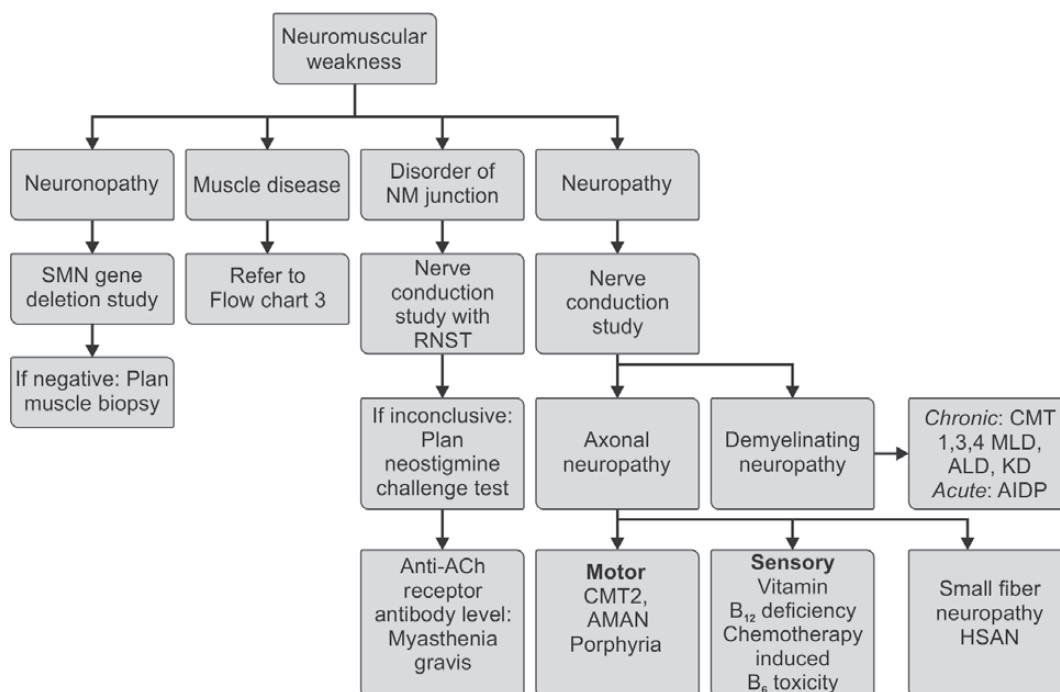
In children with suspected metabolic myopathy, forearm ischemic test is performed. Baseline arterial lactate and blood ammonia are obtained. A sphygmomanometer is applied on the arm and pressure is raised just above systolic blood pressure. The patient is asked to exercise with hands repeatedly for minimum of 1 min or till maximum fatigue. The cuff is deflated, blood samples

Flow chart 5 Broad approach to diagnosis of children with symmetrical progressive proximal weakness


for lactate and ammonia are obtained at 1 min, 3 min, 6 min and 10 min. In normal healthy patient and in children with lipid storage disorder, lactate levels increase initially for first two readings followed by decline. In children with McArdle disease, normal rise in lactate is absent. Normal rise in lactate with no rise in ammonia suggests myoadenylate deaminase deficiency.

Creatine Phosphokinase Levels

Most common first-line screening investigation in neuromuscular weakness is elevated in inflammatory muscle disease (dermatomyositis, polymyositis) and active primary muscle disease [DMD, BMD, limb-girdle muscular dystrophy (LGMD), CMD]. Moderate elevation is seen among facioscapulohumeral dystrophy, Emery-Dreifuss muscular dystrophy and congenital myopathy.

Flow chart 4 Basic laboratory approach to neuromuscular disorders


Abbreviations: CMT, Charcot-Marie-Tooth; RNST, repeated nerve stimulation test; HSAN, hereditary sensory autonomic neuropathy; AIDP, acute inflammatory demyelinating polyradiculopathy.

CPK levels are normal or mildly elevated in neuronopathies like SMA. CPK-MM is muscle specific whereas CPK-MB is cardiac specific but may also be increased in myopathy. CPK levels may be increased following trauma and electromyography (EMG) study. Hence, CPK levels must be done prior to EMG study and should be repeated over time. CPK levels may pseudonormalize in end stages of most of dystrophinopathies or if the child is on steroids.

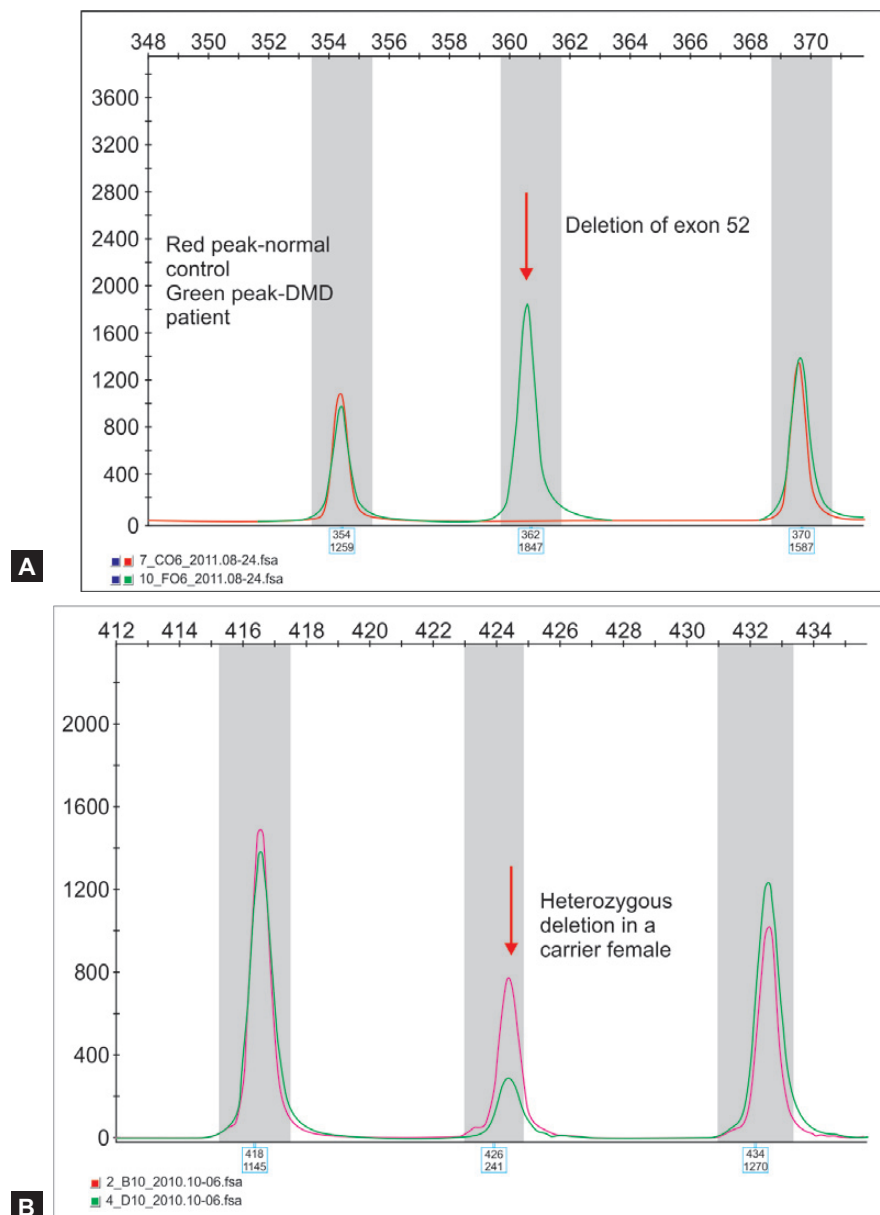
Molecular Diagnostic Testing

Molecular testing has become first line investigation among those suspected with DMD gene deletion) **(Figs 12A and B)**, SMA (*SMN1* gene deletion) **(Figs 13A and B)**, calpainopathy [Calpain 3 western blotting **(Fig. 14)**], congenital myotonic dystrophy (*DMPK* gene defect) or myotubular myopathy (*MTM1* gene defect).

Nerve Conduction Study Including Needle EMG

Neurophysiological examination of young children is difficult to apply in young and uncooperative children. It would be useful in differentiating site of lesion (nerve, muscle, neuromuscular junction) and for diagnosing myotonia. RNST can be performed to look for evidence of myasthenia. Needle EMG will assess muscle spontaneous activity, response to insertion of probe, characterization of motor unit action potential (MUAP), and rapidity with which additional motor units are recruited in response to electrical signal. EMG showing evidence of brief duration, small amplitude motor unit with increased recruitment is suggestive of myopathy. Of note, reduced NCV can be seen in patients with primary muscle disorder (CMD with merosin deficiency).

Muscle and Nerve Biopsy

Muscle biopsy is fairly essential for final diagnosis of majority of neuromuscular diseases in children unclassified by genetic testing **(Table 6)**. Muscle biopsy is ideally obtained from vastus lateralis or deltoid. Gastrocnemius muscle is avoided as tendon insertion extends through muscle, which may result in inadvertent sampling of tendon resulting in difficulty in interpretation.


Figures 12A and B (A) Deletion of Exon 52 of *DMD* gene resulting in DMD phenotype; and (B) The heterozygous deletion resulting in carrier state of DMD
Figures 13A and B (A) A child with spinal muscular atrophy and its confirmation using MLPA; (B) Polymerase chain reaction (PCR) method for analysis of survival motor neuron (SMN) Exon 7 deletion
Figure 14 Calpain-3 western blotting using anti-calpain-3 antibody (94 kDa) from patient with suspected calpainopathy. In (a), Control (C) shows band of normal molecular mass and amount. Case 1: partial calpain-3 deficiency; (b) calpain-3 degradation band

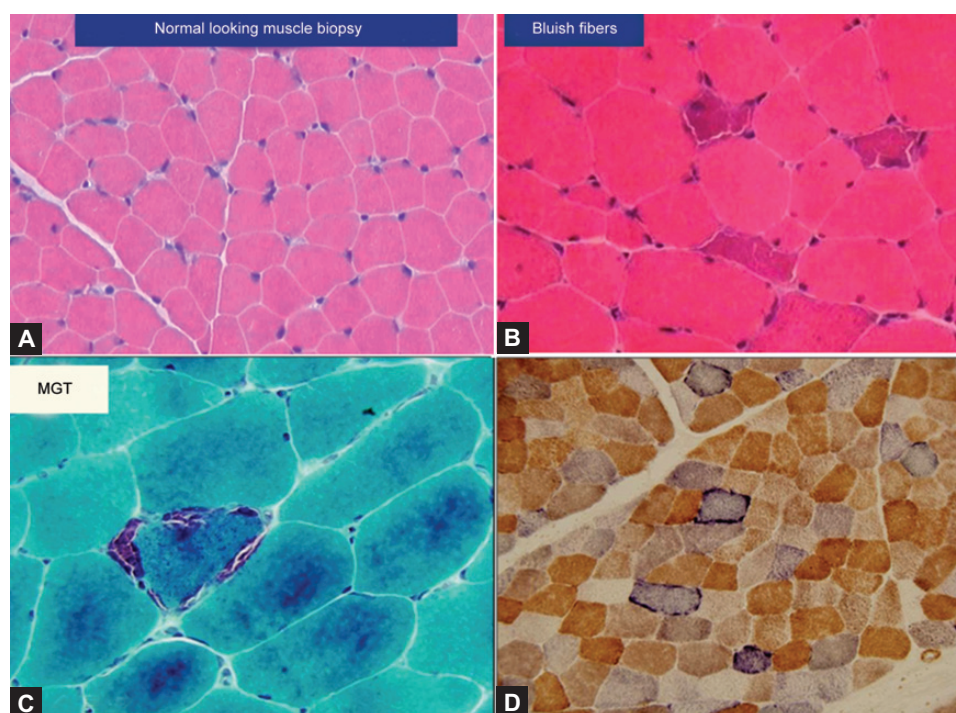
Table 6 Key features in muscle biopsy in neuromuscular disorders

Features in muscle biopsy	Neuromuscular disease
Muscle fiber necrosis with regenerative changes and replacement with fat	Dystrophies (DMD, BMD, LGMD)
Ragged red fibers with oxidative enzyme study (NADH, succinate dehydrogenase)	Mitochondrial myopathy
Inflammatory changes with mononuclear infiltrates	Dermatomyositis
Glycogen accumulation with PAS staining	Glycogen storage disease

Biopsy can be obtained by punch biopsy or open biopsy. Most of pathological centers with facilities for immunohisto-chemistry prefer receiving open biopsy samples. Muscle biopsy including immunohistochemical staining is useful in character-ization of muscular disorders [dystrophinopathy **(Figs 15A to D)**, calpainopathy **(Figs 16A to C)**, congenital myopathy **(Figs 17 and 18)** and mitochondrial disorders **(Figs 19 and 20)**]. Electron microscopy is essential for characterization of type of congenital myopathy. Ultrasonography and magnetic resonance imaging (MRI) muscle are good modalities for localizing the best site for muscle biopsy. MRI muscle with short-tau inversion recovery
Figures 15A to D Photomicrographs (case of Becker muscular dystrophy) showing features of muscular dystrophy (A, H&E x 400), mosaic pattern of immunostaining for dystrophy 1, 2 and 3 (B, C, D x 400)
Figures 17A to D Photomicrographs showing normal looking muscle in a patient of nemaline rod myopathy (A, H&E x 200); granular greenish material accruing (B, MGT stain x 400); material is immunoreactive to alfa 2 actinin (C, x 100); ultrastructural examination showed numerous rod like structures (D, x 7,500 original magnification)
Figures 16A to C Muscle biopsy from a case of calpainopathy showing features of muscular dystrophy (A and B, H&E x 100 and 400 respectively); NADH-TR stain showing numerous lobulated fibers (C, x 400)

(STIR) sequence is especially useful in inflammatory myopathies like dermatomyositis. Nerve biopsy is sometimes useful for diagnosis of hereditary motor and sensory neuropathy (HMSN) where genetic testing (*PMP22* gene deletion) is either not available or not affordable.

Skin Biopsy

It is a simple and less traumatic procedure which requires minimal sedation. It results in less traumatic scar and there are less chances of infection. Muscle biopsy being an invasive procedure and genetic testing facilities being available only in a few centers. Thus,
Figures 18A to D Multiminicore disease: Photomicrographs showing rarefaction of the cytoplasm (A, H&E x 400); numerous unstained areas on SDH and NADH-TR staining (B and C x 200); destruction and streaming of Z bands (D, x 1,650 original magnification)


Figures 19A to D: Photomicrographs (case of mitochondrial myopathy) showing normal looking muscle fibers (A, H and E x 200) and bluish fibers which appear as ragged red fibers with MGT stain and COX negative but SDH positive with COX/SDH stain (B and C, x 400; D, x 200)

a diagnostic test that is easily available, simpler, and less invasive is desirable. Over the past 2 decades, skin biopsy has been evolving as a suitable option. Skin biopsy can substitute for muscle biopsy as the preliminary diagnostic tool directing appropriate molecular testing. However, further studies are required to determine if skin biopsy can hold promise for the future. Skin biopsy can be used for screening dystrophinopathy in muscular dystrophy patients (high sensitivity and positive predictive value). It being a simple and minimally invasive procedure, histopathologic and molecular markers of disease progression and response to novel treatment options can be assessed serially **(Figs 21 and 22)**.

Enzyme Analysis

Metabolic myopathy requires enzymatic study for confirmation. Enzyme analysis includes Muscle phosphorylase deficiency (McArdle disease) and acid maltase deficiency (Pompe disease). Tandem mass spectrometry is required for diagnosis of carnitine palmitoyltransferase (CPT) deficiency and other more uncommon metabolic defects.

Antibody Testing

In children with suspected myasthenia gravis, acetyl choline receptor antibody (AchR Ab) and anti-MuSK antibody are essential
Figure 20 Electron microphotograph showing zipper-like paracrystalline inclusions in the mitochondria (x 8,500 original magnification)
Figure 21 H and E staining of skin biopsy showing arrector pili muscle (H and E x 400)
Figures 22A to E Skin biopsy of DMD patient showing normal arrector pili muscle with loss of dystrophin 1, 2, 3 and upregulation of utrophin (H and E x 400)
Figure 23 T1-weighted axial MRI image at the level of thigh shows fatty infiltration and atrophy of posteromedial group of muscles in a child with calpainopathy

for diagnosis of juvenile myasthenia gravis. Similarly, antimyositis antibodies (Anti Jo-1, Anti Mi2, Anti Ro 52) are useful supportive investigation for diagnosis of dermatomyositis.

MRI Brain

Central nervous system should be screened among children with merosin deficient CMD and alpha-dystroglycanopathies (Muscle-Eye-Brain disease, WWS, Fukuyama CMD. Magnetic resonance spectroscopy (MRS) is useful in suspected mitochondrial myopathy.

Muscle Ultrasound and Muscle MRI

Magnetic resonance imaging (MRI) and ultrasonography muscle (Neuromuscular imaging) is being used increasingly to characterize the severity and pattern of muscle involvement in inherited neuromuscular disorders. It has emerged as an important noninvasive adjunct to diagnosis of neuromuscular diseases. Although, it is essential to emphasize that muscle biopsy remains the gold standard for establishing the diagnosis. Characteristic patterns on muscle MRI helps in differentiation of dystrophy versus nondystrophic muscle; characterize the pattern (selective involvement of certain group of muscles) for narrowing the differentials in congenital myopathy and LGMD. The patterns of muscle atrophy, intramuscular fibrosis and fatty infiltration can be detected using muscle ultrasonography. In addition, it can visualize the muscle movement, contraction and fasciculations. DMD is known to result in severe inhomogenous increase of muscle echointensity with normal thickness whereas SMA causes inhomogenous increase in muscle intensity with atrophy. Similarly, calpainopathy results in fatty infiltration and atrophy of posteromedial group of muscles **(Fig. 23)**.

IN A NUTSHELL

1. Neuromuscular commonly presents as floppiness in infancy and gait difficulty with proximal or distal weakness.
2. While approaching a child with suspected neuromuscular disease ascertain its mode of inheritance, onset and progression of weakness, extent of weakness and selective involvement of muscle groups to reach to a broad diagnosis.
3. Once a clinical diagnosis and neuroanatomical localization is made, laboratory investigations should be chosen judiciously with key focus on noninvasive investigations like genetic testing if available.
4. Molecular diagnostic testing remains the mainstay for diagnosis in children suspected with SMA, Duchenne muscular atrophy, congenital myotonic dystrophy and other pediatric neuromuscular diseases.
5. Role of NCV and EMG is limited to differentiating site of lesion (nerve, muscle, neuromuscular junction), to diagnose myotonia and to ascertain the type of neuropathy (axonal or demyelinating).
6. Majority of congenital myopathies and other types of muscular dystrophies require muscle biopsy with immunohistochemistry and electron microscopy for confirmed diagnosis.
7. Consider the newer emerging investigations like skin biopsy, muscle MRI and muscle ultrasonography when indicated.

Chapter 43.2
Floppy Infant
Anaita Udwadia-Hegde, Shilpa Kulkarni

The term *floppy infant* indicates multiple disorders with various degrees of hypotonia which can be axial, appendicular or both. For the same reason it is helpful to divide the localization into two broad groups: (1) the supraspinal conditions (including the brain, brainstem and cervical spinal junction) that can be called *central hypotonia* and the segmental conditions, which are more appropriately called *motor unit hypotonia* (including anterior horn cell, peripheral nerve, neuromuscular junction and muscle). The physician must also ascertain whether the delay, when present, is just a motor delay or motor and cognitive delay together. The differential diagnosis is vast and includes a number of disorders ranging from benign conditions with good prognosis to life-threatening disorders that are incompatible with life. A systematic approach is essential for diagnosis in order to avoid unnecessary investigations.

Floppiness can be secondary to hypotonia, weakness and ligamentous or joint laxity. But *floppy baby* should be restricted to hypotonia only. The cerebral cortex, cerebellum, basal ganglia are all involved in supranuclear control of tone but the final pathway is through the lower motor neuron unit.

LOCALIZATION OF HYPOTONIA

Hypotonia may be central, developmental or peripheral in origin. A systematic approach to a child who has hypotonia, with emphasis on history and clinical examination is essential in localizing the problem. **Figure 1** depicts localization of the origin of hypotonia with examples.

It is important to distinguish weakness from hypotonia. While hypotonia is reduced resistance to passive movements around a joint, weakness is reduction in the maximum power that can be generated. Thus, floppy infants exhibit poor control of movements, delayed motor skills, alteration of postural control, increased range of motion of joints and abnormal stability. Weak infants always have hypotonia but hypotonic infants may not have weakness.

There are mainly two approaches to the diagnostic problem. The first is based on neuroanatomical localization, i.e., central nervous system (CNS) or peripheral nervous system involvement and their subsequent subdivisions as cerebral cortex, cerebellum in the CNS as against nerve, muscle, neuromuscular junction or anterior horn cell in the peripheral nervous system.

The second is to determine whether or not the hypotonia is associated with weakness. Hypotonia of central origin may be associated with weakness, while hypotonia with profound weakness usually suggests involvement of the lower motor neuron unit. Central causes account for 60–80% of hypotonic cases while peripheral causes account for 15–20%. Some disorders can cause both central and peripheral manifestations such as Pompe's disease.

Some clinical features common to most floppy babies regardless of the etiology or location of the abnormality are highlighted in **Table 1**.

APPROACH TO DIAGNOSIS

History Taking

History regarding pregnancy and neonatal period These include consanguinity, previous fetal losses, low fetal kick count and
Figure 1 Localization of the origin of hypotonia
1. Cerebral cortex   2. Basal ganglia   3. Brainstem   4. Cerebellum
5. Spinal cord   6. Anterior horn cell   7. Myoneural junction
8. Muscle

Table 1 Clinical features of a floppy infant

Frog-like posture	Poor quality of spontaneous movements with legs fully abducted and arms lying by the side of body either flexed or extended
Pull to sit	Excessive head lag and rounded back
Vertical/Axillary suspension testing	Minimal support with a sensation of *slipping through the hands*
Ventral suspension	Inverted U position/ragged doll posture
Drooling and oropharyngeal pooling of secretions	Poor swallowing ability
Weak cry	Respiratory weakness
Paradoxical breathing pattern	Intercostal muscles paralysis usually with intact diaphragm
Inefficient cough	Intercostal muscles weakness
Plagiocephaly, flat occiput, arthrogryposis, and other congenital anomalies like dislocation of hip, CTEV	Decreased fetal movements
Signs of impairment in level of consciousness, feeding difficulties, seizures, apneas, abnormal posturing, abnormalities of ocular movements and of brain-stem reflexes	Features suggestive of severe CNS abnormalities and a sick floppy infant

quality of fetal movements, polyhydramnios, prolonged labor, breech presentations and emergency cesarean sections. History in the newly born of respiratory difficulties in the recovery room, need for resuscitation or ventilation problems in early infancy, infantile hypotonia, weak cry and poor feeding. Also newborn clues include any history of umbilical hernias, congenital talipes equinovarus, joint dislocations, contractures and arthrogryposis.

A detailed feeding history from birth may provide valuable diagnostic clues. Several genetic disorders may present with hypotonia, including Prader-Willi syndrome, which in later childhood shows hypotonia, obesity, mental retardation and hypogonadism but is characterized in infancy by feeding difficulties and failure to thrive. A diagnosis of infantile botulism may be prompted by a history of honey or corn syrup consumption; contamination of these products with *Clostridium botulinum* may account for significant amount of botulism cases during infancy.

Getting family details and a pedigree chart are imperative to diagnosis so as to assist with future genetic counseling.

History regarding onset, duration and progress of the weakness Acute onset (days to weeks) or chronic (months to years). Whether episodic? Is the weakness getting worse, staying the same, or getting better? Ascertain the rate of progression (days, weeks, months, or years).

Detailed history of the child's acquisition of developmental milestones Ascertain when the child was able to control his or her head, sit independently, crawl, stand with and without support, walk with and without support, gain fine pincer grasp and acquire bimanual skills (bringing objects to midline and transfer of objects). Obtain history regarding language acquisition and school performance.

Functional difficulties Identify factors that worsen or help the primary symptoms. Obtain history of fatigue or lack of endurance and muscle cramps or stiffness and any associated pain. Ask for ambulatory distances (it is useful to time prefixed distances walked at each visit for a prospective analysis); frequency of falls; transition from the floor to standing; problems in ascending and descending stairs; problems in dressing; problems reaching above the head; difficulty lifting; running ability; problems in physical education and recreational or athletic performance.

Systemic symptoms History of recent illnesses (e.g., recent viral illnesses, respiratory difficulties, pneumonia, pulmonary infections); cardiac symptoms (dizziness, syncope, chest pain, orthopnea, cardiac complaints with exertion); pulmonary symptoms (breathing difficulties, sleep disturbance, morning headaches); anesthetic history (e.g., malignant hyperthermia).

It is important to distinguish between congenital and acquired hypotonia from the history. For example, a child who becomes floppy on day 3–5 of life may be due to an inborn error of metabolism. **Table 2** summarizes a few historical clues to differentiate origin of weakness.

Physical Examination

General appearance A head-to-toe detailed general physical examination is required to assess for potentially associated organ dysfunction and to recognize existing syndromes. Dysmorphic features sharply increase the likelihood of CNS dysfunction as an explanation for hypotonia, although a long, narrow face may indicate muscle weakness (**Fig. 2**: Myopathic facies). Anterior horn

Table 2 Historical clues to differentiate origin of hypotonia

Historical clues suggestive of hypotonia of central origin	Historical clues suggestive of hypotonia of peripheral origin
• Social and cognitive impairment in addition to motor delay • Failure of visual tracking or failure to imitate facial gestures, appears lethargic • Dysmorphic features implying a syndrome or other organ malformations sometimes implying a syndrome • Features that may suggest an underlying spinal dysraphism • History suggestive of hypoxic-ischemic encephalopathy, birth trauma • Hypoglycemia and other metabolic disturbances • Seizures, depressed level of consciousness, abnormal eye movements, irregular/exaggerated breathing pattern	• Delay in motor milestones with relative normality of social and cognitive development (however, features of central nervous system involvement like dysmorphism, impaired vision and hearing, seizures and cognitive impairment can be seen in syndromic congenital muscular dystrophy) • Family history of neuromuscular disorders/ maternal myotonia

Figure 2 Typical myopathic facies

cell disease usually spares extraocular muscles, while diseases of the neuromuscular junction may be characterized by ptosis and extraocular muscle weakness. Attention to the quality of the cry is pivotal because a high-pitched or shrill cry suggests a CNS pathology, a weak cry may reflect diaphragmatic weakness and a fatigable cry may suggest a congenital myasthenic syndrome.

Physical examination of the parents This provides important diagnostic information, especially as a parent may have very mild symptoms of a serious disorder. For example, transitory neonatal

myasthenia may be suspected if the mother displays fatigability of the eyelids with upward gaze or fatigability of the arms with sustained forward extension. Infants with congenital myotonic dystrophy have severe hypotonia but their mothers are typically only mildly affected and unaware of their disorder. Mothers with myotonic dystrophy may show grip myotonia, percussion myotonia, ptosis and/or distal weakness that they were unaware of.

Systemic examination Abnormalities of other organs such as the heart or liver are more likely to be associated with a number of metabolic diseases. In the presence of hypotonia, signs of cardiac failure suggest muscle or mitochondrial disease. Hepatosplenomegaly suggests a lysosomal or glycogen storage disease. Renal cysts, high forehead, wide fontanelles are suggestive of Zellweger syndrome. Hepatomegaly and retinitis pigmentosa is seen in neonatal adrenoleukodystrophy. Congenital cataracts and glaucoma is seen in oculocerebrorenal (Lowe) syndrome. Abnormal odors are suggestive of various metabolic disorders.

Neurological assessment The clinician should review the child's posture, head shape, size and spontaneous movements along with assessment of the higher functions and cognition. In assessing tone, the child should be alert but not crying. Extremity tone is readily assessed by passive movements. Floppy infants often lie with their limbs abducted and extended along with plagiocephaly, due to the head on one side. The techniques to help elicit abnormal tone are discussed here and shown in **Figures 3A to C**.

- *Pull to sit (traction)* The infant is pulled by the arms from supine to sitting—wherein there is severe head lag with a rounded back suggestive of poor axial tone.
- *Ventral suspension* The infant is suspended in the prone position with examiner's palm underneath his abdomen and chest—the head, legs and arms flop limply by the side in an inverted U shape.
- *Vertical suspension* The infant is held under his arms in the vertical position by the examiner's finger and tends to *slip through*.
- *Scarf sign* is performed by grasping the supine infant's hand and pulling it across the chest as far as it will go without significant resistance. Normally, the elbow can be brought to the midline of the baby's chin and chest. In the hypotonic infant, the elbow can easily be brought well beyond the midline before encountering resistance. This test measures the appendicular tone in the shoulder and is sensitive to the gestational age of the infant, the degree of laxity of the ligaments and the state of alertness of the child.
- *Prone position* The infant looks flopped out in a typical frog-like posture with inability to come up and bear weight on the upper limbs and face turned to one side.

Table 3 depicts localization of disorders producing hypotonia. The deep tendon reflexes are likely the most valuable aspect of the physical examination. Brisk reflexes or clonus indicate CNS dysfunction, while diminished or absent reflexes point strongly to disorders of the lower motor unit.

Other features, which may be noted are poor axial tone, poor balance, delay in weight bearing, decreased resistance to flexion and extension, abnormal stability, truncal sway, W sitting, wide-based gait, genu recurvatum and hyperextensible joints.

Boxes 1 and 2 highlight some features associated with central and peripheral causes of hypotonia, respectively.
Figures 3A to C Examination techniques to elicit floppiness. (A) Pull to sit demonstrating severe head lag; (B) Ventral suspension demonstrating inverted U shape; (C) Vertical suspension demonstrating the infant tending to *slipping through*

---

BOX 1 Clinical features suggestive of hypotonia of central origin

- Predominantly axial weakness
- Fisting of hands
- Normal strength with hypotonia
- Normal or brisk deep tendon reflexes, persistent neonatal reflexes
- Pseudobulbar palsy, brisk jaw jerk, crossed adductor/scissoring on vertical suspension.

BOX 2 Clinical features suggestive of hypotonia of peripheral origin

- Reduced or absent spontaneous antigravity movements with increased range of movements
- Reduced or absent deep tendon reflexes
- Myopathic facies: Open mouth with tented upper lip, poor lip seal, lack of facial expression, ptosis/restricted ocular movements
- Frog-leg posture
- Fasciculations (diagnostic of anterior horn cell disease)
- Muscle atrophy/pseudohypertrophy
- Presence of respiratory and feeding impairment.

DIFFERENTIAL DIAGNOSIS

There are a host of conditions associated with infantile hypotonia. **Table 4** lists the different conditions in two broad categories namely central and peripheral causes of hypotonia. The differentiation whether the hypotonia is static or progressive, helps in deciding if we are looking at a neurodegenerative disorder. Also differentiating into the hypotonic infant whether is a sick or a well-floppy infant is useful. Genetic disorders, e.g., Down's syndrome children are well looking and hence categorize into the well-floppy infant group. On the other hand, all the causes of acute encephalopathies

presenting with floppiness are usually sick children with a sinister prognosis.

Differential diagnosis of hypotonia in neonatal and infancy period is summarized in **Table 4**. There are certain conditions where both central and peripheral hypotonia may coexist **(Box 3)**. In most studies, central causes account for 60–80% of hypotonia cases and peripheral causes occur in 15–20%.

Most common central cause of hypotonia in early infancy is hypoxic-ischemic encephalopathy (HIE) followed by malformations. A large percentage is due to genetic or syndromic conditions of which Down's syndrome is the most common. Not many studies have been done in India and quoting one study evaluating the clinical profile of paralytic floppy infants found that spinal muscular atrophy was the most common peripheral cause of floppy children (60%) followed by congenital myopathy, and congenital muscular dystrophy which was similar to the profile seen worldwide then.

Most genetic conditions are associated with hypotonia presenting from infancy. The common ones are Prader-Willi syndrome, Trisomy 18, Velo-cardio-facial syndrome, Williams's syndrome, Cri-du-chat syndrome, etc.

Nonsyndromic central hypotonia These patients do not have a recognizable collection of somatic dysmorphic features but still have anomalies or abnormalities of the CNS that result in hypotonia. They can be placed into two major categories based on the neuroimaging (MRI) findings:

1. *With MRI evidence of developmental abnormalities of the brain* These are most often less specific, minor anomalies and are classified as types of cerebral dysgenesis. They may

Table 4 Differential diagnosis of hypotonia in neonatal period and infancy

Central causes	Peripheral causes

• Acute encephalopathies
  – Birth trauma
  – Hypoxic-ischemic encephalopathy
  – Hypoglycemia
• Chronic encephalopathies
  – Cerebral malformations
  – Inborn errors of metabolism (Mucopolysaccharidoses, aminoacidurias, organic acidurias, lipidoses, fatty acid oxidation defects, glycogen storage diseases, Menke's disease, primary carnitine deficiency)
  – Chromosomal disorders (Prader-Willi syndrome, Trisomy 21, Trisomy 13 and 18, Cri-du-Chat syndrome, DiGeorge syndrome)
  – Genetic disorders (Familial dysautonomia, Lowe syndrome, deletion and duplications and single gene disorder)
  – Peroxisomal disorders (Neonatal adrenoleukodystrophy, Zellweger syndrome)
  – Endocrine (hypothyroidism)
  – Metabolic (rickets, renal tubular acidosis)
  – Connective tissue disorders (Ehlers-Danlos syndrome, osteogenesis imperfect, congenital ligamentous laxity, benign congenital hypotonia)
• Cerebellar disorders
• Hydrocephalus
	• Spinal muscular atrophy**
	• Paralytic poliomyelitis
	• Neuropathies
	  – Hereditary motor-sensory neuropathy
	  – Congenital hypomyelinating neuropathy
	  – Acute demyelinating polyneuropathy
	• Neuromuscular junction problems
	  – Botulism
	  – Transient neonatal myasthenia
	  – Autoimmune myasthenia
	  – Congenital myasthenic syndromes
	  – Magnesium toxicity
	  – Aminoglycoside toxicity
	  – Periodic paralysis
	• Muscular disorders
	  – Congenital myopathies (Nemaline rod myopathy, myotubular myopathies, central core disease, minicore disease, etc.)
	  – Congenital muscular dystrophies (CMD) (Walker-Warburg, Fukuyama, muscle-eye-brain disease, merosin-positive CMD, early infantile facioscapulohumeral dystrophy, etc.)
	  – Congenital myasthenic syndromes
	  – Congenital myotonic dystrophy
	  – Metabolic myopathies (Acid maltase deficiency, phosphorylase deficiency, mitochondrial myopathy)
	  – Endocrine myopathies (hypothyroidism)

**Spinal muscular atrophy—have alert inquisitive facies

• Hypoxic-ischemic encephalopathy
• Infantile neuroaxonal degeneration
• Lipid storage diseases
• Lysosomal disorders
• Mitochondrial disorders
• Perinatal asphyxia secondary to motor unit disease.

---

or may not have delayed myelination on the MRI. These children are hypotonic though tone may improve with maturation.

2. *No obvious evidence of cerebral dysgenesis* Some of these infants will be delayed in the development/maturation of myelin. Clinically, the children with delayed myelination fall into two broad groups. One group has hypotonia with motor delay and normal language and social skills. They tend to slowly catch up with their peers and although will have some deficit in motor coordination. The second group is globally delayed. They do

not usually catch up in motor and cognitive skills and have difficulties if they are expected to function in a normal school setting. Children with central hypotonia without any cerebral dysgenesis and delayed myelination can also be divided into two groups just as those with delayed myelination with a similar prognosis.

INVESTIGATIONS

Once localization to central or peripheral cause is decided, then further investigations can be planned. In case of *central hypotonia*, depending on the case, the choice of investigation is neuroimaging—for which MRI is distinctly preferred. Portable ultrasound may be used for acute management especially in the intensive care setting. Karyotype, fluorescence in situ hybridization (FISH), microarray or specific genetic tests, metabolic screening and endocrine testing may also be processed. The metabolic screening should include thyroid function studies in all hypotonic infants as hypothyroidism is one of the common and treatable causes of floppy infant.

If peripheral causes are suspected, first investigation would be creatine phosphokinase (CPK) followed by electrophysiology such as electromyography (EMG), nerve conduction study (NCS) and repetitive nerve stimulation. EMG studies are used as an important diagnostic tool to differentiate whether the disorder is myopathic, neuropathic or a denervating process. It is also helpful to decide central and peripheral causes of hypotonia. Muscle and nerve biopsy is the gold standard for structural myopathies and peripheral neuropathies. Areflexia, decreased limb movements, fasciculations detected clinically and denervation on EMG should prompt investigation straightway for anterior horn cell disorders (spinal muscular atrophy), which can be confirmed by testing for the homozygous deletion of exon 7 in the telomeric survival motor neuron gene. The diagnosis of congenital myotonic dystrophy is confirmed by testing for the expanded cytosine-thymine-guanine (CTG) trinucleotide repeat sequence on chromosome 19q13.2–q13.3. Failure to find electrophysiological abnormalities should prompt the clinician to suspect the diagnosis of Prader-Willi syndrome. The diagnosis of congenital myasthenic syndromes allows for DNA testing in some of the common syndromes. Some congenital muscular dystrophies are associated with brain abnormalities, thus neuroimaging may be required in these patients. **Table 5** serves as a guide in planning the investigations for floppy infants. **Flow chart 1** depicts an overview of evaluation for a floppy infant.

TREATMENT

Treatment of the infant who has hypotonia must be tailored to the specific condition. In general, therapy is supportive. Few conditions have specific treatment. These include hypothyroidism (thyroxine), some types of congenital myasthenic syndromes (pyridostigmine or neostigmine) and rickets (vitamin D). Some metabolic disorders may respond to specific dietary modifications or enzyme replacement therapies. Rehabilitation is an important aspect with aid of physical and occupational therapists. Nutrition is of primary importance, often achieved through nasogastric or percutaneous gastrostomy tubes for additional caloric supplementation. It also is important to maximize muscle function and minimize secondary crippling anatomic deformities. Prenatal diagnosis using amniocentesis or chorionic villus sampling is often feasible if a definitive diagnosis has been reached in the index case.

Cerebral injury/Dysgenesis

• MRI Brain
• EEG
• Infection screen (CSF, Blood)
• Ophthalmology examination

Genetic causes

• Karyotyping
• FISH analysis
• Methylation studies
• CGH Array

 Inborn errors of metabolism

• Toxic encephalopathies
   Plasma ammonia
   Amino acids (Blood, Urine)
   Urine organic acids
   Blood acylcarnitine profile
   Plasma uric acid
   Urinary sulfites
   Enzyme assays in skin fibroblasts

• Mitochondrial
   Plasma lactate, DNA depletion studies
   Respiratory chain analysis (Muscle)
   DNA based mutation analysis

• Lysosomal, e.g., Pompe's disease
   Lysosomal enzyme assay in WBC,
   Skin biopsy examination for inclusions,
   Skin fibroblast cultures plus enzyme assays
   ECG, Electrocardiography

• Perioxisomal disorders, e.g., Zellweger's
   syndrome, phytanic acid, plasma VLCFA

• Congenital disorders of glycosylation
   Isoimmune electrophoresis for transferrin

Endocrine

• Thyroid function tests

Motor neuron

• CPK Levels
• EMG/NCV
• Genetic analysis—SMN gene analysis

Nerve

• EMG/NCV
• Nerve biopsy
• Genetic mutation analysis

Neuromuscular junction

• EMG/NCV with repetitive stimulation
• Acetylcholinesterase antibodies
• Genetic analysis

Muscle

• Muscle enzyme studies
  (CPK, Aldolase, LDH)
• Muscle biopsy
• Genetic mutation studies

Abbreviations: MRI, magnetic resonance imaging; CPK, creatine phosphokinase; EEG, electroencephalography; EMG, electromyography; NCV, nerve conduction velocity; CSF, cerebrospinal fluid; SMN, survivor motor neuron; VLCFA, very long-chain fatty acid; LDH, lactate dehydrogenase.

Table 5 Clinical clues and investigations in floppy infants

Condition	Clinical clues	Investigations
Spinal cord transection or syringomyelia or other forms of spinal dysraphism	• Hemangioma or tuft of hair in midline disease • Scoliosis • Evidence of bladder or bowel dysfunction • Mixed deep tendon reflexes with absent abdominal and anal reflexes	• MRI spinal cord
Spinal muscular atrophy	• Tongue atrophy and fasciculations • Severe proximal muscle weakness with absent tendon reflexes • Preserved social interaction	• *EMG/NCV*: Anterior horn cell involvement • Deletion of the survival motor neuron (*SMN*) gene by PCR testing
Peripheral neuropathy	• Weakness predominantly distal • In most cases absent deep tendon reflexes studies • Pes cavus	• Motor nerve conduction studies • Sural nerve biopsy • Molecular DNA testing is available for specific demyelinating disorders
Myasthenia gravis	• Greater involvement of oculomotor and bulbar muscles • True congenital myasthenia due to receptor defects is rare • Exclude transient neonatal form from maternal history	• Response to acetylcholinesterase inhibitors • Single-fiber EMG • Serum antibodies to acetylcholine receptors • Electrodiagnostic studies not universally positive in young patients
Infantile botulism	• Acute onset descending weakness, cranial neuropathies, ptosis, stool culture unreactive pupils, dysphagia, constipation	• Isolation of organism from stool culture • Presence of toxin in the stool
Congenital muscular dystrophy	• Hypotonia, weakness and contractures • Associated brain and eye problems • Brain MRI for structural and white matter abnormalities	• Creatine kinase usually elevated • *Muscle biopsy*: Merosin stain
Congenital myotonic dystrophy	• Polyhydramnios with reduced fetal movements • Inverted V-appearance of the mouth • Examination of mother's face shows inability to bury her eyelashes and grip myotonia • Premature cataract surgery in the mother • Slender stature	• Molecular DNA testing by determining number of CTG repeats (normal range 5–39 repeats) • EMG of the mother
Congenital structural myopathy	• Hypotonia with feeding problems at birth • Weakness that is often nonprogressive *Nemaline myopathy*: Often associated with feeding problems *Central core*: Most often associated with malignant hyperthermia *Myotubular myopathy*: Ptosis and extraocular palsies consistent clinical features	• CK and EMG usually not helpful • Muscle biopsy is critical for definitive diagnosis • ECG • Genetic mutation studies
Glycogen-storage disease Pompe's disease	• Enlarged heart in a very floppy weak newborn • Unexplained cardiac failure • Tongue may appear large	• Blood smear vacuolated lymphocytes • Urine oligosaccharides • Typical ECG and ECHO changes • Acid maltase assay in cultured fibroblasts • Muscle biopsy usually not necessary

Abbreviations: EMG, electromyography; NCV, nerve conduction velocity; PCR, polymerase chain reaction; CTG, cytosine thymine guanine; CK, creatine kinase.

IN A NUTSHELL

1. Floppy infant is suggestive of hypotonia.
2. Hypotonia is not synonymous with weakness.
3. Hypotonia can be of central (damage, dysgenesis, genetic, metabolic) or peripheral (anterior horn cell, peripheral nerve, neuromuscular junction, muscle) in etiology.
4. History and examination are the keys to deciphering the cause of the hypotonia.
5. Investigations should be tailored to the suspected cause.
6. Central causes are most common with HIE still the most common single cause followed by genetic syndromes.

Chapter 43.3
Acute Flaccid Paralysis
Biswaroop Chakrabarty, Sheffali Gulati

Acute flaccid paralysis (AFP) is defined by a clinical syndrome characterized by rapid onset of weakness which at times is accompanied by bulbar and respiratory muscle weakness. The term *flaccid* indicates that the affected patient is hypotonic. Epidemiologically these cases are relevant in view of surveillance for poliomyelitis. There is no fixed duration cited in literature for rapidity of evolution and progression of clinical features to nadir. It is usually mentioned in days to weeks. The most probable explanation for this is that by keeping a liberal and open-ended definition, the chance of missing out on these epidemiologically significant cases will be minimal. Moreover, it is crucial to identify all these cases at the earliest as many of them respond dramatically to immunotherapy and delay in diagnosis and treatment may lead to significant morbidity and mortality.

BACKGROUND AND PUBLIC HEALTH IMPORTANCE

In 1988, World Health Organization (WHO) resolved for global eradication of poliomyelitis by the end of 20th century. AFP surveillance is a key strategy in that endeavor, which is a sensitive instrument for detecting poliovirus infection. From the perspective of global polio eradication initiative, AFP is defined as a case of AFP in children less than 15 years of age or paralytic illness in a patient of any age when polio is suspected. Reporting of all AFP cases less than 15 years of age is mandatory in India. All AFP cases should be investigated within 48 hours of reporting. Two stool samples should be collected from such cases at 24–48 hours apart intervals, transported and then processed at WHO accredited laboratories for virus isolation. These cases should be followed up to 60 days for any residual paralysis. The sensitivity of AFP reporting is determined by the proportion of cases with two stool samples collected within 2 weeks after onset of paralysis (ideally > 80%) and by reporting of nonpolio AFP cases in children less than 15 years of age (at least 1/1,00,000 children in 1 year). *The National Polio Surveillance Project* was started in 1997 in India. India has been declared polio free in January 2014 (last case reported 13th January 2011).

ETIOLOGY

The causes of AFP vary according to age and geographic location of patients. Anatomical localization to specific parts of the nervous system underlies the pathophysiology in distinct clinical entities. The various areas implicated in nervous system include anterior horn cell, peripheral nerves and radicles, spinal cord, neuromuscular junction and muscle. The various causes implicated in AFP according to various anatomical sites are outlined in **Table 1**.

INITIAL APPROACH TO A CHILD WITH AFP

A child with AFP is a medical emergency. The key steps in initial management are as follows:
- *Respiratory care* It is essential to check for respiratory involvement in the form of rapid breathing, shallow or

Table 1 Anatomical localization and etiological agents in acute flaccid paralysis

Anatomical site	Etiology
Anterior horn cell	Poliovirus, nonpolio enterovirus, Japanese B encephalitis
Dorsal root ganglia	Herpes simplex virus, cytomegalovirus, rabies
Spinal cord	Acute transverse myelitis, parasitic infestation (*Schistosoma*, Cysticercus, *Echinococcus*), space occupying lesions, anterior spinal artery syndrome, trauma, postcardiovascular surgery vascular complications
Radicles and peripheral nerves	Guillain-Barré syndrome, chronic inflammatory demyelinating polyneuropathy, HIV infection per se or associated opportunistic infections or complications (herpes simplex virus, cytomegalovirus, Epstein-Barr virus, zoster, *Giardia lamblia*, *Toxoplasma gondii*, *Mycobacterium tuberculosis*, *Treponema pallidum*), vitamin B_{12} deficiency, nucleoside antiretroviral agents, hepatitis B, diphtheria, rabies, tick bite, borreliosis, heavy metals (lead, arsenic, thallium, gold), chemotherapeutic agents (colchicine, vinca alkaloids, cisplatin), organic solvents including glue sniffing, critical illness, hypokalemic (acute symptomatic and familial) and thyrotoxicity
Neuromuscular junction	Myasthenic crisis, organophosphorus poisoning, drugs (aminoglycoside, phenytoin), botulism, Elapidae snake envenomation and critical illness
Muscle	Polymyositis, systemic lupus erythematosus, mixed connective tissue disorder, viral (HIV, nonpolio enteroviruses, human T-cell lymphotropic viruses), toxoplasmosis, Lyme's disease, trichinosis

Abbreviation: HIV, human immunodeficiency virus.

paradoxical respiratory efforts and use of accessory muscles. Early respiratory support and intubation is crucial in final outcome of these children.
- *Bulbar weakness detection and management* Patients should be monitored for pooling of secretions, ineffective or weak cough, nasal regurgitation of feeds and fluids, nasal intonation of voice and choking. Regular suctioning and nasogastric feeding should be practiced whenever indicated.
- *Managing cardiovascular instability* These patients are prone to develop cardiac rhythm disturbances. Under ideal circumstances, ECG electrodes should be attached to all AFP patients.
- *Rule out dyselectrolytemia and snake envenomation* At presentation, hypokalemia and snake bite should be ruled out as they have treatment implications.
- *Rule out spinal cord pathology* It is crucial to enquire for and rule out spinal cord disease as early decisions like immobilization of the patient, administration of corticosteroids and neurosurgical intervention can be taken.

CLINICAL ASSESSMENT

Once a patient with AFP is initially stabilized and all emergent measures are taken, a detailed clinical evaluation (history and examination) is obligatory to reach to a definite diagnosis.

Onset of paralysis Very rapid onset within hours to few days may be seen in Guillain-Barré syndrome (GBS), traumatic injection sciatic neuropathy, transverse myelitis, botulism, myasthenic crisis, viral myositis, periodic paralysis and occasionally in critical illness polyneuropathy. Onset within 2–3 weeks is seen in polio and nonpolio enteroviruses, varicella zoster virus, Japanese B encephalitis, tick bite paralysis and trichinosis. In entities like postdiphtheritic polyneuropathy, Lyme's disease and polymyositis the onset is in weeks to months whereas in rabies the onset may take months to years.

Progression of paralysis Maximum deficit at onset is seen in traumatic injection sciatic neuropathy. In polio and nonpolio enteroviruses, transverse myelitis, botulism, myasthenic crisis, periodic paralysis, viral myositis and critical illness polyneuropathy, the progression to nadir is within hours to few days. Progression up to 2–4 weeks is seen in GBS, varicella zoster virus, Japanese B encephalitis, rabies, tick bite paralysis and trichinosis. The paralysis may progress from few weeks to months in Lyme's disease and polymyositis. Classically ascending paralysis is described with GBS, rabies, varicella zoster virus and tick bite whereas descending variant is seen with botulism and diphtheria.

Topography of paralysis Asymmetric involvement is seen with polio and nonpolio enteroviruses, Japanese B encephalitis and traumatic injection sciatic neuropathy. Symmetric distribution of paralysis is seen in rabies, varicella zoster, GBS, transverse myelitis, botulism, diphtheria and tick bite paralysis. Proximal involvement more than distal is seen in polio and nonpolio enterovirus infection, Japanese B encephalitis, periodic paralysis and polymyositis, otherwise it is mostly a diffuse widespread involvement. Associated cranial neuropathy is seen in GBS (facial weakness), diphtheria (palatal and ocular palsy), botulism (ocular and bulbar palsy), tick bite paralysis (ocular palsy), Lyme's disease (facial weakness) and myasthenic crisis (ocular and bulbar palsy). Early respiratory muscle weakness is seen in periodic paralysis, critical illness polyneuropathy, high cervical myelopathy and occasionally in GBS and postdiphtheritic polyneuropathy.

Sensory features Sensory signs and symptoms (paresthesia, hypoesthesia, anesthesia) are seen in neuropathy secondary to neurotropic viruses (rabies, varicella zoster and Japanese B encephalitis), GBS, transverse myelitis (sensory level with band like sensation demarcating that level), postdiphtheritic polyneuropathy, Lyme's disease, postinjection traumatic sciatic neuropathy and critical illness polyneuropathy.

Deep tendon reflexes Areflexia is seen in diseases of anterior horn cell, peripheral nerves and radicles and in the spinal shock phase of cord diseases. However in spinal cord disorders, once a patient is out of spinal shock phase, then hyperreflexia is demonstrable below the level of lesion. Reflexes are usually preserved in neuromuscular junction disorders and myositis (may be hyporeflexic occasionally in the latter).

Bladder bowel involvement Early bladder and bowel involvement (urinary retention and constipation) is seen in transverse myelitis. Occasionally this is seen in rabies and GBS and rarely in poliomyelitis.

Fever at onset of paralysis This feature is seen with polio and nonpolio enteroviruses, other neurotropic viruses, occasionally with transverse myelitis, viral myositis, trichinosis and critical illness polyneuropathy.

Etiology specific features Trivial trauma leading to myelopathy should raise the suspicion of an underlying cervical vertebral instability. Enquiry should be made for exposure to heavy metals like lead and arsenic, animal bite and snake envenomation. Preceding prodromal illness and history of vaccination is seen in parainfectious causes like GBS and transverse myelitis. Specifically history should be taken for fever, sore throat with bull neck to rule out diphtheria, particularly in unimmunized children. History of preceding diarrhea is important particularly in the setting of hypokalemia or enteroviral infection. Exertion induced or postprandial acute onset of paralysis should raise the suspicion of periodic paralysis. History of preceding intramuscular injection is important in the setting of polio or unilateral sciatic neuropathy.

Other systemic features Fatigable weakness showing diurnal variation or long-term fluctuation suggests underlying myasthenia. Nonspecific prodromal illness at onset is seen in poliomyelitis. Hand, foot and mouth disease is seen with nonpolio enteroviruses whereas exanthematous vesicular eruptions are seen in varicella zoster infection. Meningeal signs are seen in polio and nonpolio enteroviruses, GBS and acute transverse myelitis. Associated pain is seen in polio and nonpolio enterovirus and other neurotropic virus infection, GBS, transverse myelitis, Lyme's disease, viral myositis, polymyositis, trichinosis and critical illness polyneuropathy. Systemic manifestation secondary to autoimmune diseases and lymphoreticular malignancies can be seen in polymyositis. Abdominal pain, rash and neuropsychiatric manifestations point towards underlying porphyria. In critical illness, polyneuropathy underlying critical sickness is present like sepsis, shock or cardiorespiratory failure.

The clinical features in a child with AFP for common causes are summarized in **Table 2**.

MANAGEMENT

In most instances, a child with AFP reaches an emergency medical service. At the first contact only, the work of AFP surveillance should be initiated at the earliest. Two stool samples should be collected from such cases at 24–48 hours apart intervals, transported and then processed at WHO accredited laboratories for virus isolation. Along with this, emergency medical measures as already mentioned should be undertaken wherever and whenever indicated.

INVESTIGATIONS

It is essential to rule out potentially treatable conditions. According to the clinical scenario, in this regard, the following investigations can be done.

- Serum potassium
- Magnetic resonance imaging spine with contrast (to rule out acute transverse myelitis, traumatic, vascular or infectious pathology of the spinal cord) **(Fig. 1)**

Table 2 Summary of clinical features in a child presenting with acute flaccid paralysis

Disease	Onset	Progression	Topography	DTRs	Sensory features	Bladder and bowel involvement	Fever at onset	Systemic features	Etiological clues
Polio and nonpolio enteroviruses	2–3 weeks	Hours to few days	Asymmetric pure motor involvement with proximal > distal	–	–	Rare	+	Meningeal signs, nonspecific prodromal illness, hand, foot and mouth disease in nonpolio group	Attack precipitated by IM injection
Rabies	Months to years	2–4 weeks	Symmetric, ascending, generalized	–	+	Occasional	+	Bite mark	History of animal bite
GBS	Hours to few days	2–4 weeks	Symmetric, ascending, generalized, cranial neuropathy (commonly VIIth), occasionally early respiratory weakness	–	+	Occasional	±	Meningeal signs occasionally	Preceding prodromal illness or vaccination
ATM	Hours to few days	Hours to few days	Symmetric, generalized, respiratory involvement in high cervical lesions	Absent (in spinal shock phase), brisk below the level of lesion later	Sensory level present	Early	±	Meningeal signs occasionally	Preceding prodromal illness or vaccination
Post-traumatic sciatic neuritis	Hours to few days	Maximum deficit at onset	One limb involved	Absent in that limb	+	–	–		Preceding history of IM injection
Postdiphtheritic polyneuropathy	Weeks to months	2–4 weeks	Symmetric, descending, generalized, cranial neuropathy (commonly palatal), occasionally early respiratory weakness	–	+	±	–	Cardiomyopathy	Preceding history of fever with neck swelling (bull neck) and membranous pharyngitis
Botulism	Hours to few days	Hours to few days	Symmetric, descending, generalized, cranial neuropathy (ocular and bulbar), occasionally early respiratory weakness	–	±	–	–		
Tick bite paralysis	2–3 weeks	2–4 weeks	Symmetric, generalized, cranial neuropathy (ocular)	–	–	–	–	Bite mark	History of travel to endemic areas
Viral myositis	Hours to few days	Hours to few days	Symmetric, generalized, painful	Normal or reduced	–	–	+		Viral prodrome
Hypokalemic periodic paralysis	Hours to few days	Hours to few days	Symmetric, proximal > distal, early neck flexor and respiratory weakness	–	–	–	–		Precipitated by postprandial state or exertion
Critical illness polyneuropathy	Hours to few days	Hours to few days	Symmetric, generalized, early respiratory involvement	–	–	–	±	Underlying sepsis, shock, cardiorespiratory failure	

Abbreviations: DTRs, deep tendon reflexes; GBS, Guillain-Barré syndrome; ATM, acute transverse myelitis; –, absent; +, present; IM, intramuscular.
Figure 1 Magnetic resonance imaging (MRI) spine T2-weighted image shows altered signal changes (marked by red arrow) in the dorsolumbar spine characteristic of myelitis

Figure 2A Nerve conduction study showing features of demyelination (reduced conduction velocity and distal latency of motor nerve action potential)

- *Electrophysiology*: Nerve conduction study (NCS) (in suspected GBS case and also to delineate various subtypes whether demyelinating, axonal, motor, sensory or mixed) **(Figs 2A and B)**, repetitive nerve stimulation test (RNST) in suspected cases of myasthenia, NCS and electromyography in traumatic sciatic neuropathy
- Cerebrospinal fluid examination (in GBS albuminocytological dissociation is documented by the end of 1st week and beyond, if pleocytosis is present, conditions like Lyme's disease, HIV and enteroviral myelitis should be suspected)
- Serum creatine phosphokinase (in suspected cases of viral myositis)
- Urine for porphobilinogen in suspected porphyria cases
- Urine and serum toxicology screen for lead and arsenic if their toxicity is suspected
- Lyme's serology.

Apart from these treatable conditions, the above-mentioned investigations would also help to diagnose conditions which do not have definite therapy and the mainstay of treatment is supportive care. The clinical picture leading to diagnostic approach in AFP is diagrammatically depicted in **Flow chart 1**.

TREATMENT

Emergency care This has already been discussed in detail in the section, *Initial approach to a child with AFP*.

Definitive Care
This category includes treatment options which are curative.

Intravenous immunoglobulin (IVIG) Indicated in GBS and myasthenic crises (2 g/kg/day, divided over 4–5 days in once daily dosage).

Pulse methylprednisolone therapy 30 mg/kg/day (maximum: 1 g) for transverse myelitis.

Anti-snake venom in suspected cases of envenomation.

Intravenous potassium for hypokalemia.

Figure 2B Nerve conduction study showing features of axonal involvement (reduced amplitude of motor nerve action potential)

Definite treatment for porphyria and heavy metal toxicity (lead, arsenic) if clinical picture and investigations are suggestive.

Supportive Care

Prevention of bedsores Position change and air-filled mattresses should be practiced to prevent development of this complication.

Bladder and bowel care In cases of urinary retention, clean intermittent catheterization (CIC) should be practiced. In constipation, apart from nutritional modifications and laxatives, enema is indicated in refractory cases and when there are palpable fecoliths.

Nutrition Proper calorie and protein intake along with mineral and vitamin supplementation should be ensured. In case of bulbar dysfunction, patient should be put on oro- or nasogastric feeds.

Flow chart 1 Clinical features leading to investigations in a child with acute flaccid paralysis (AFP)

A child with AFP

| Sensory level, paraparesis, early bladder dysfunction | Cranial neuropathy ± respiratory and autonomic involvement ±, areflexia, sensory deficits ±, bladder involvement ± | Febrile, pure motor, asymmettic, meningismus | Preceding history of injection (usually within 24 hours), 1 limb affected no sensory deficits | Proximal weakness, pain, no sensory features, DTRs usually preserved |

Transverse myelitis

- GBS (ascending paralysis, usually VII, IX, X, XI, XII cranial neuropathy)
- Postdiphtheritic polyneuropathy (appropreate clinical setting, palatal palsy)
- Botulism (descending paralysis, ophthalmoparesism sensory ±)
- Tick bite paralysis (appropriate clinical setting, ascending, ocular involvement, no sensory deficits)
- Critical illness polyneuropathy (appropriate clinical setting, cranial neuropathy rare)
- Hypokalemic paralysis (appropriate clinical setting, early neck flexor weakness)
- myasthenia (predominant ocular and bulbar involvement, periodic fluctuation, diurnal variation)
- Rabies (ascending paralysis, autonomic instability common, appropriate clinical setting)

Nonpolio enteroviral infection

Traumatic/injection neuritis

Polymyositis, viral myositis

MRI Spine with contrast

Electrophysiology (NCS, EMG)

- Serum CPK
- Work up for underiying eltiology in polymyositis

AFP: Acute flaccid paralysis
DTR: Deep tendon reflexes
CPK: Creatine phosphokinase
EMG: Nerve conduction studies
EMG: Electromyogram
RNST: Repetitive nerve stimulation tet
CSF: Cerebrospinal fluid

- Electrophysiology (NCS, RNST)
- CSF Study

Physical and occupational therapy In the acute phase, stretching is advised to prevent development of contractures. If beyond the acute phase sequelae sets in, detailed, tailor made to individual needs, physical and occupational therapy is advised.

To conclude, AFP is both a medical and public health emergency. AFP surveillance and reporting is of paramount importance. Clinically lesions are localized to varied locations which include spinal cord, anterior horn cell, peripheral nerves, neuromuscular junction and muscles. Any child presenting with AFP should have respiratory, cardiac and bulbar involvement ruled out. It is imperative to rule out potentially treatable conditions at the earliest.

MORE ON THIS TOPIC

Marx A, Glass JD, Sutter RW. Differential diagnosis of acute flaccid paralysis and its role in poliomyelitis surveillance. Epidemiol Rev. 2000;22:298-316.
Singhi SC, Sankhyan N, Shah R, Singhi P. Approach to a child with acute flaccid paralysis. Indian J Pediatr. 2012;79:1351-7.

IN A NUTSHELL

1. Acute flaccid paralysis is defined by a clinical syndrome characterized by rapid onset of weakness occasionally accompanied by bulbar and respiratory muscle weakness.
2. Acute flaccid paralysis surveillance and reporting is of significant epidemiological significance, particularly because of its relevance in poliomyelitis surveillance.
3. The causes of AFP vary according to the age and geographical location of the patient and anatomical localization of the lesion.
4. Initial stabilization of an AFP patient is crucial. Respiratory, cardiac and bulbar dysfunction should be ruled out immediately.
5. Potentially treatable conditions like GBS, transverse myelitis, myasthenia, porphyria, heavy metal toxicity, dyselectrolytemia and snake envenomation should be ruled out at the earliest.
6. A detailed history and clinical examination can provide clues to the underlying etiology in most of the cases.
7. Apart from emergency and definitive care, supportive care is of utmost importance as a determinant of outcome in these children.

Chapter 43.4
Guillain-Barré Syndrome
Vrajesh Udani

Landry first described the clinical picture in 1856 and in 1916 Guillain-Barré and Strohl described the cerebrospinal fluid (CSF) albumino-cytological dissociation and the delayed/absent tendon reflexes characteristic of the disease. Similarities to the inflammatory demyelinating changes seen in animal experimental allergic neuritis was reported by Asbury and co-workers in 1969. In the 1990s, it was realized that Guillain-Barré syndrome (GBS) has more types than the typical demyelinating neuropathy, when acute motor axonal neuropathy (AMAN) was described from China. In the new millenium anti-ganglioside antibodies were discovered associated with different variants of GBS (see below).

EPIDEMIOLOGY

Guillain-Barré syndrome has emerged as the major cause of acute flaccid paralysis (AFP) after the worldwide decline of poliomyelitis. The incidence in less than 18 years is 0.34–1.34 cases/100,000/year which is about half of that in adults. The average age is 4–8 years and is rare below the age of 2 years. Males appear more susceptible in all GBS variants. There are two major types—(1) the AMAN variety which often has seasonal peaks and (2) the acute inflammatory demyelinating polyneuropathy (AIDP) which appears to lack this seasonal variation.

PATHOPHYSIOLOGY

Both forms of the disease are immune mediated with involvement of both humoral and cell-mediated mechanisms. Triggers are mainly environmental pathogens like viruses—common ones noted include Epstein-Barr (EB) virus, cytomegalovirus (CMV), hepatitis A and B, varicella, enteroviruses as well as *Mycoplasma pneumoniae. Campylobacter jejuni*, a Gram negative bacteria and a leading cause of diarrhea, appears particularly important as a trigger especially in the AMAN variant **(Fig. 1)**. In one Indian study, 28% of GBS was linked to this organism probably due to poor sanitation and close contact with animals. Vaccinations like influenza, hepatitis B confer an increased risk of GBS. The recent worldwide immunization with the H1N1 vaccine in 2009 resulted in an increased incidence of 0.8 cases/million doses.

These triggers are believed to activate CD4[+] helper-inducer T-cells, which act against a variety of specific endogenous antigens, including myelin P-2, ganglioside GQ1b, GM1, and GT1a, etc. Resemblance of the triggering pathogens to antigens on peripheral nerves (i.e., molecular mimicry) leads to an overzealous autoimmune response mounted by T-lymphocytes and macrophages. Activated T-cells stimulate B-cells to produce specific antiganglioside antibodies and/or recruit macrophages as effector cells. Cytokines and chemokines released by activated T-cells or complement activation may increase capillary permeability facilitating transmigration of more macrophages and result in more myelin or axonal injury.

The location of the target antigen be it myelin or axon would decide the clinical syndrome—whether AIDP, AMAN or the Miller-Fisher syndrome (MFS). Certain antibodies are seen more frequently in some clinical syndromes, e.g., anti-GM1 and anti-GD1a antibodies in AMAN and the anti-GQ1b antibodies in MFS. However, the antigen involved in AIDP still remains unknown.

Why specific antibodies lead to specific clinical syndromes is not entirely clear but may be due to distribution and density of particular antigens, e.g., GQ1b is prominent in oculomotor nerves explaining ophthalmoplegia in MFS while GM1 is more in ventral rather than dorsal roots explaining the motor neuropathy in AMAN.

CLINICAL FEATURES

A progressive ascending symmetrical paralysis coming on over hours, days, to a few weeks is the hallmark of GBS. Pain and refusal to walk are often presenting symptoms especially in preschool children (65%) and can often lead to misdiagnosis of other non-neurologic painful conditions. Frequent radicular involvement is manifested by the positive straight leg-raising sign (SLR). Early areflexia especially the loss of ankle jerk is usual though occasionally jerks may persist especially in the AMAN variant. Bladder symptoms occur in about 10% but are usually transient.

Cranial nerve involvement typically bifacial palsy occurs in half while bulbar palsy with dysphagia, drooling and dysphonia occurs less commonly. Ophthalmoplegia is exceptional except in the Miller-Fisher variant where ataxia and areflexia form the triad. Autonomic manifestations are seen in up to one-third with dizziness, hypertension and arrhythmia.

The most dreaded complication is respiratory muscle weakness which can come on rapidly, especially in the AMAN variant and leads to the occasional mortality. About 10–15% of patients need mechanical ventilation on the whole though this number is higher in the AMAN variant.

Clinically, AMAN and ADIP could be remarkably similar though AMAN is probably more rapid in its evolution with higher grade of severity and more patients needing ventilation. MFS typically is a milder disease with full rapid recovery and will rarely be admitted to an intensive care unit (ICU). Diagnostic criteria for GBS and what makes the diagnosis of GBS doubtful is outlined in **Tables 1 and 2**, respectively.

Atypical Variants

Polyneuritis cranialis is an acute disorder with multiple cranial neuropathies usually including bilateral seventh cranial nerves with high CSF protein and slowed nerve conduction velocities (NCVs) with rapid recovery. It is associated with previous CMV infection.

Acute motor and sensory axonal neuropathy is rare and is similar to AMAN but with sensory involvement as well. The course is more severe.

A *pharyngo-cervical-brachial variant* where the paralysis involves bulbar, neck and upper limb muscles early and then may descend.

Respiratory muscle weakness may sometimes predominate initially necessitating early ventilation where the diagnosis may be at times confused with acute respiratory conditions.

Locked-in state An occasional patient may look comatose due to severe quadriplegia and pan-cranial neuropathy where a locked-in state prevents the patient from responding to any stimuli.

Acute pandysautonomia pure sensory variant Where there is predominant autonomic or sensory involvement. Both these variants are rare.

Painful variant In young children, a predominantly painful variant with minimal/no obvious weakness and preserved reflexes may lead to confusion with other medical conditions. Recovery is usually complete.
Figure 1 Immunopathogenesis of Guillain-Barré syndrome: molecular mimicry and anti-ganglioside antibodies. Infections (e.g., *Campylobacter jejuni*) can trigger humoral immune responses resulting in nerve dysfunction. Lipo-oligosaccharides on the *C. jejuni* outer membrane elicits antibodies which cross-react with gangliosides on peripheral nerves. The antigens in AMAN are located at the node of Ranvier and anti-GM1 and anti-GD1a antibodies bind to the axolemma leading to complement activation and formation of MAC leading to nerve damage. Macrophages scavenge the injured axons. In AIDP, the antigens are presumably located on the myelin sheath and induce injury to Schwann cells and myelin sheaths by a similar mechanism.

Abbreviations: AIDP, acute inflammatory demyelinating neuropathy; AMAN, acute motor axonal neuropathy; APC, antigen presenting cell; GBS, Guillian-Barré syndrome; MAC, membrane attack complex.

Table 1 Criteria for the diagnosis of typical Guillain-Barré syndrome (GBS) (adapted from Asbury)

Features required for diagnosis
• Progressive weakness in both arms and both legs • Areflexia
Features strongly supporting diagnosis
• Progression of symptoms over days to 4 weeks • Relative symmetry of symptoms • Mild sensory symptoms or signs • Cranial nerve involvement, especially bilateral weakness of facial muscles • Recovery beginning 2–4 weeks after progression ceases • Absence of fever at onset • High concentration of protein in cerebrospinal fluid, with fewer cells than 10×10/L • Typical electrodiagnostic features • Pain (is often present).

Table 2 Features that should raise doubt about the diagnosis of GBS

• Marked persistent asymmetry of weakness
• Bladder or bowel dysfunction at onset
• Persistent bladder or bowel dysfunction
• Sharp sensory level
• Severe pulmonary dysfunction with limited limb weakness at onset
• Severe sensory signs with limited weakness at onset
• Fever at onset of neurological symptoms
• Increased number of mononuclear cells in CSF ($> 50 \times 10^6$/L)
• Polymorphonuclear cells in CSF

DIFFERENTIAL DIAGNOSIS

Nonpolio Enteroviral and Other Viral Myelitis

As poliomyelitis is now eradicated in India, *viral myelitis* is now caused mainly by nonpolio enteroviral (NPEV) and occasionally by other viruses like Japanese B encephalitis and West Nile viruses. NPEV typically have fever, pain, meningeal signs bladder involvement and asymmetric paralysis usually involving proximal lower limb muscles. *Vaccine associated paralytic poliomyelitis* may also cause a similar picture. CSF pleocytosis is usually present in the 1st week though albumin-cytologic dissociation pictures are also reported. Recovery is often incomplete. Diagnosis is by stool culture as part of government-sponsored AFP surveillance.

Around 20–30% of *rabies* victims (especially if vaccinated) present as a febrile patient with acute ascending paralysis and bladder involvement. The diagnosis becomes rapidly clear as central nervous system (CNS) involvement becomes obvious.

Acute Myasthenic Crisis and Other Neuromuscular Disorders

This occasionally can be the first manifestation of immune *myasthenia gravis* and may be confused with atypical GBS/MFS with predominant involvement of ocular, bulbar and respiratory muscles. A normal CSF, electrodecremental response on repetitive nerve stimulation and positive antiacetylcholine receptor antibody clarifies the diagnosis easily.

Botulism is the other neuromuscular-junction disorder which may be considered but it is extremely rare in our part of the world. Pupillary involvement is typical and helps to differentiate it from GBS where pupillary reflexes are normal.

Neurotoxicity of *snake-bite* involves extraocular muscles and respiratory muscles and must be considered in the differential diagnosis especially in rural regions.

Acute Transverse Myelitis

This clinical syndrome can be confused with GBS in younger children where sensory levels are difficult to ascertain. Persistent urinary retention usually helps to differentiate. Areflexia is the rule in the acute stage like in GBS. Spinal magnetic resonance imaging (MRI) helps easily differentiate the two.

Acute compressive myelopathies especially involving the conus medullaris may occasionally mimic GBS as they present with lower limb hypotonia, areflexia and pain.

Other Neuropathies

Acute intermittent porphyria should always be considered in school-age children/teenagers who present with AFP along with severe abdominal pain. Hyponatremia, hypertension and encephalopathy help to differentiate this from AMAN. Increased excretion of urinary porphobilinogens provides an answer.

Rarely in infants neuropathies associated with disorders like *metachromatic leukodystrophy* and *Leigh's syndrome* may present subacutely without obvious CNS involvement and hence get confused with GBS. Typically uniform symmetric slowing of NCV vis-à-vis the nonuniform patchy involvement in GBS suggests these diagnoses.

Acute Cerebellar Ataxia

Young children who suddenly stop walking do so due to either pain, weakness (as in GBS) or ataxia and it is sometimes difficult to differentiate these in a crying fretful toddler. Ataxia is more likely if there is no loss of antigravity movements in the supine position especially with preserved reflexes.

Antalgic Conditions

Pain and weakness often coexist in GBS. Many antalgic conditions present with inability to walk or stand unsupported and it is often difficult to differentiate whether pain or weakness is the predominant factor causing this symptom. Antalgic conditions encompass diverse disorders like synovitis, discitis, scurvy or even leukemia and must be carefully excluded if clinically suspected.

LABORATORY DIAGNOSIS

High CSF protein without a cellular response—so-called albumin-cytologic dissociation may take up to a week though changes are usually seen around 48 hours after onset. Sometimes there is a cellular response of up to 50 cells which can suggest a viral etiology. GBS associated with human immunodeficiency virus (HIV) typically has a significant CSF pleocytosis.

Nerve conduction studies peak in the 2nd week though some specific changes may be seen in the 1st week like absence of late responses, etc. Hence, the problem with both CSF and NCV is that they may be normal in the 1st week of illness. Recently spinal and sometimes cranial contrast MRI has gained popularity as changes are seen within 2 days in greater than 90% of children. Typically the ventral roots of the cauda equine show enhancement.

Antibodies to different ganglioside antigens are positive in about half of Asian/Indian patients. This positivity is more specific in AMAN and MFS. These are however not useful in early diagnosis.

TREATMENT

Plasma exchange (PE) and intravenous immunoglobulin (IVIG) have been shown to be equally effective in hastening recovery in all GBS including childhood GBS. However, the ease of administration of IVIG as well as less adverse effects makes this the first-line treatment in childhood GBS. Studies have typically involved more severely affected patients and the dosage used has been high dose 2 g/kg. Whether milder affected ambulant patients benefit from IVIG is not really studied though small studies using PE did hasten recovery in adults. Also, in a resource-poor country like ours, we need to study whether lower doses of IVIG would suffice. It is not known whether IVIG given later than 2 weeks after onset of disease would hasten recovery as all studies have used early treatment; however, treatment up to 4 weeks is common practice.

Some patients continue to deteriorate in spite of PE or IVIG. How to manage the deteriorating patient is not really known. PE followed by IVIG is not really superior to IVIG or PE alone. Whether to give PE following initial IVIG is not known. Corticosteroids have not been shown to hasten recovery and oral steroids may actually delay recovery.

Some patients have worsening after initial improvement—the so-called *treatment-related clinical fluctuation*. It is common practice to repeat IVIG. If these clinical fluctuations occur more than three times or if the recovery has not occurred 9 weeks into illness, one must consider the acute variant of chronic inflammatory demyelinating polyneuropathy (CIDP).

ICU Management

Children need transfer to ICU in the presence of any of the following: Rapidly progressive disease, bulbar dysfunction, autonomic instability, weakness of shoulder shrugging, reduction of vital capacity (VC) greater than 30% of baseline; VC less than 20 mL/kg, maximal inspiratory pressure (PI max) less than 30 cm H_2O, or maximal expiratory pressure (PE max) less than 40 cm H_2O (20/30/40 rule). PFT parameters are difficult to use because most patients do not cooperate; serial single breath counts appear more reliable and anything less than a count of 15 would be a red flag.

Generally, arterial blood gases (ABGs) are not reliable in deciding elective intubation as they tend to change late. Sleep related oxygen saturations less than 90% should be a cause for concern. Cardiac and BP monitoring is important. One should not be too aggressive in treatment of hypertension/tachycardia as sometimes dramatic reversals occur suddenly especially with beta-blockers. Thrombo-embolic complications due to prolonged immobilizations are uncommon in children but low-molecular weight heparin prophylaxis may sometimes be needed.

PROGNOSIS

In general, the outcome in children is excellent. Mortality is unusual nowadays with modern intensive care. However, in developing countries, the mortality is still reported between 11% and 13%. Though the AMAN variant reaches a more severe disability stage than AIDP and has a higher rate of respiratory failure needing ventilation, the final outcome at 12 months is excellent in both groups. MFS generally has a good prognosis and does not need immunotherapy unless it overlaps with GBS.

IN A NUTSHELL

1. Guillain-Barré syndrome has emerged as the major cause of AFP after the worldwide decline of poliomyelitis. The average age of affected children is 4–8 years.
2. There are two major types: (1) the AMAN variety which often has seasonal peaks and (2) the AIDP which appears to lack this seasonal variation.
3. Both forms of the disease are immune mediated with involvement of both humoral and cell-mediated mechanisms.
4. A progressive ascending symmetrical paralysis coming on over hours, days, to a few weeks is the hallmark of GBS.
5. High CSF protein without a cellular response—albumin-cytologic dissociation and delayed NCVs are characteristic.
6. Immunotherapy with IVIG and intensive care has made this once-dreaded disease into an eminently treatable condition with an excellent long-term outcome.

Chapter 43.5
Spinal Muscular Atrophy
Soumya Sundaram, Muralidharan Nair

The spinal muscular atrophy (SMA) is a group of genetically determined neuromuscular disorders due to degeneration of anterior horn cells of spinal cord with or without involvement of bulbar motor neurons. Clinically they present with progressive pure lower motor neuron type of weakness characterized by symmetric proximal muscle involvement of all four limbs, wasting of muscles, fasciculations and absent deep tendon reflexes. The onset of weakness may occur at any age, from birth to adult life. Some spinal muscular atrophies show a generalized distribution of weakness, and others affect specific muscle groups. Werdnig and Hoffman independently described SMA in 1890s and the culprit gene *survival of motor neuron (SMN)* gene was identified a century later.

Various neuromuscular disorders like congenital muscular dystrophy, congenital myopathy, congenital myasthenia syndrome, congenital myotonic dystrophy and hereditary neuropathy present in a manner similar to SMA and the treating clinician should be able to differentiate them accurately as to avoid missing any treatable causes.

EPIDEMIOLOGY

The incidence of SMA is one in 6,000–10,000 livebirths and the carrier frequency is 1 in 50, which makes SMA one of the most common fatal autosomal recessive disorders. The epidemiological data from India is scanty and the findings from a hospital based observational study from eastern India showed that SMA patients constituted 20% of cases among motor neuron diseases.

ETIOLOGY

Spinal muscular atrophy results from the homozygous deletion of survival of motor neuron 1 gene (*SMN1*). There are two identical *SMN* genes present on chromosome 5q12.2–q13.3 which is designated as *SMN1* and *SMN2*. There are two copies each of *SMN1* and *SMN2* genes in normal individuals. Earlier they were termed telomeric (*SMN1*) and centromeric (*SMN2*) survival motor neuron genes. *SMN* gene codes for SMN proteins which are ubiquitously expressed and are localized in both cytoplasm and nucleus. SMN proteins are abundant in the motor neurons of the spinal cord which explains why these neurons are preferentially degenerated in SMA.

SMN1 Gene
SMN1 gene encodes *SMN1* protein, which is a 38kD polypeptide. SMN protein is a part of high molecular weight protein complex (SMN complex) which is necessary for the proper assembly of Smith class core proteins in Uridine rich small nuclear ribonuclear proteins (UsnRNP). UsnRNP are principal components of spliceosomes which execute the splicing of the pre-mRNA to produce functional mRNAs. Homozygous deletion of *SMN1* gene results in *SMN1* protein reduction and alters UsnRNP assembly and mRNA splicing. SMN may also play a key role in axonal transport in anterior horn cells.

SMN2 Gene
The coding region of *SMN2* differs from *SMN1* in a single base pair, which codes for a truncated and unstable protein. The deletion of *SMN2* alone does not produce SMA; however, the number of *SMN2* copies will determine the severity of SMA. Patients with SMA type 1 have only one copy of *SMN2*, those with intermediate SMA have two copies and those with the adult form have three or four copies of *SMN2* genes. This clearly shows that less the number of copies of *SMN2* gene, more is the severity of the disease.

CLINICAL SUBTYPES

The clinical subtypes of autosomal recessive SMA are in continuum of disease spectrum. The International SMA consortium meeting in 1992 had classified SMA into four types **(Table 1)** based on age of onset and the highest function achieved.

Spinal Muscular Atrophy Type 0
Spinal muscular atrophy type 0 (SMA0) manifests before birth, i.e., in utero as decreased fetal movement. Affected newborns have generalized weakness involving proximal more than distal muscles, hypotonia and areflexia. Newborns may have difficulty adapting to extrauterine life and experience postnatal asphyxia and encephalopathy due to significant respiratory muscle weakness. Despite intrauterine hypotonia, arthrogryposis is not present.

Spinal Muscular Atrophy Type 1 (Early Infantile Form, Werdnig-Hoffman Disease)
Spinal muscular atrophy type 1 (SMA1) is the most common which constitutes 50% of the SMA. SMA1 patients present in the neonatal period or within 6 months of life and will never attain the ability to sit independently. The disease is fatal and they usually die before 2 years of age.

These children present as floppy infants characterized by severe generalized hypotonia, proximal more than distal weakness

Table 1 International SMA Consortium classification of spinal muscular atrophy

SMA type	Genetics	Age of onset	Clinical features	Maximum function achieved	Prognosis
0 Prenatal	*SMN* gene AR	Intrauterine	Reduced fetal movements Respiratory distress at birth	Requires ventilatory support at birth	Fatal at birth
1 Infantile SMA (Werdnig-Hoffmann)	*SMN* gene AR	0–6 months	Floppy infant Bulbar and respiratory involvement	Sits with support	Death by 2 years of age
2 Intermediate SMA	*SMN* gene AR	6–18 months	Delayed motor milestones	Sit without support Unable to walk	Variable
3 Juvenile SMA (Kugelberg-Welander)	*SMN* gene AR	After 18 months	Pseudomyopathic pattern	Able to walk with assistance	Variable
4 Adult SMA	*SMN* gene AR	Usually after 30 years (Above 5 years)	Pseudomyopathic pattern/ neuropathic pattern	Able to walk independently	Slow progression Normal lifespan

Abbreviation: AR, autosomal recessive.

and areflexia. Due to severe hypotonia, infants assume *frog-leg position* while lying supine and have head lag on traction test. The *frog-leg* position occurs due to severe hypotonia and at rest baby assumes a characteristic position with the thighs externally rotated and abducted with the knees flexed. When pulled from a supine to a seated position, these children are unable to lift their heads and demonstrate severe head lag **(Fig. 1)**. Deep tendon reflexes are usually absent and the sensory examination is normal. Fingers may have polyminimyoclonus which are fine, small amplitude involuntary movements due to dense fasciculations. Bulbar motor neuron involvement results in progressive feeding difficulty, weak cry and tongue fasciculations. Extraocular movements are always normal. Intercostal muscles are severely weak, but diaphragm involvement occurs late in the disease. Respiratory distress in these children is due to intercostal muscle weakness and aspiration pneumonia. Contractures may develop after several months of immobilization. Oculofacial muscle sparing and an active alert child help the clinician to distinguish SMA from other causes of hypotonia in infants.

Cardiac abnormalities like atrial and ventricular septal defects, although uncommon has been described in severe SMA. Prognosis is bad as they usually die before 2 years of age due to respiratory failure and aspiration pneumonia.

Spinal Muscular Atrophy Type 2 (Late Infantile Form, Intermediate Form)

Spinal muscular atrophy type 2 (SMA2) patients are normal at birth and usually present to the clinicians as delayed motor milestones with normal language and social milestones. The age of onset is between 6 months and 18 months and they are able to sit unsupported with variable bulbar and respiratory involvement. Lower limb weakness is more than arm weakness and the disease progression is slower than SMA1. Most children eventually are able to roll over and sit unsupported. Some of them are able to acquire standing position but they never achieve independent walking. They have prominent hip and knee contractures, kyphoscoliosis, club feet and bilateral polyminimyoclonus. Weakness of trunk muscles produces kyphosis and scoliosis. Eventually patients become wheelchair confined. The clinical severity and prognosis vary markedly with some patients dying early because of respiratory failure and others surviving into adulthood.

Figure 1 A 7-month-old baby with spinal muscular atrophy. There is significant head lag when the baby is being pulled up by pull to sit maneuver denoting hypotonia

Spinal Muscular Atrophy Type 3 (Juvenile Form, Kugelberg-Welander Disease)

Spinal muscular atrophy type 3 (SMA3) patients are normal at birth and they manifest motor weakness after 18 months of age. Although they attain independent walking ability, they develop slowly progressive limb-girdle pattern of weakness with lower limbs more affected than upper limbs. They have difficulty in climbing stairs, getting up from squatting position and use Gower's maneuver to do so. They develop waddling gait (Trendelenburg's sign) with excessive lumbar lordosis and protuberant abdomen. Neck and truncal muscle weakness develop later. Pseudohypertrophy of the calf muscles occurs sometimes which is due to relative preservation of calf muscles as compared to thigh muscles. The clinical profile resembles limb-girdle muscular dystrophy, but the presence of wasting, fasciculations and areflexia helps to differentiate from a primary muscle disease. The fasciculations in the SMA3 are much more pronounced than in SMA1 and SMA2. SMA3 has two subtypes based on age of onset:

1. Spinal muscular atrophy type 3a (SMA3a) in whom the age of onset is between 18 months and 3 years. They have a more severe course and lose ambulation earlier when compared to spinal muscular atrophy type 3b (SMA3b).
2. Spinal muscular atrophy type 3b is designated when the age of onset is after 3 years. They have milder phenotype and are mostly ambulant with or without assistance.

Spinal Muscular Atrophy Type 4 (Adult Onset, Pseudomyopathic Type)

The adult onset SMA was earlier termed as pseudomyopathic type due to resemblance with limb-girdle muscular dystrophy. Spinal muscular atrophy type 4 (SMA4) usually occurs after 30 years of age and the clinical features are similar to intermediate type with limb-girdle pattern of involvement. The patient initially manifests with difficulty in climbing stairs or getting up from squatting position. Later they have buckling of knee due to quadriceps weakness which is often a prominent feature. Upper limb involvement occur late; bulbar, respiratory involvement and bony deformities are rare. Proximal muscles are wasted and 75% of these patients have fasciculations. Muscle cramps can occur but are not a prominent feature. There is no ophthalmoparesis or ptosis and muscle stretch reflexes are absent. They remain ambulatory for decades and majority have a normal lifespan.

Variants of SMA not due to *SMN* Gene Mutations

Some of the genetic causes of anterior horn cell are due to mutations other than *SMN* gene involvement, but they have almost similar phenotype to SMA with some atypical features **(Table 2)**. They have autosomal dominant, autosomal recessive or X-linked inheritance patterns.

Spinal muscular atrophy with congenital arthrogryposis and bone fractures Spinal muscular atrophy with congenital arthrogryposis and bone fracture is an SMA variant which manifests in utero with decreased fetal movement, multiple joint contractures and bone fractures at birth. They require ventilatory support for survival at birth.

Fazio-Londe disease Fazio-Londe disease is a rare childhood onset form of atypical SMA with autosomal dominant or autosomal recessive inheritance. The predominant muscle groups affected are facial and bulbar. The affected children are normal at birth but develop progressive bulbar palsy and eventual respiratory failure in the 2nd decade of life. There is no evidence of involvement of other motor neurons or the extraocular muscles.

Finkel type SMA Finkel type SMA is similar to typical adult onset SMA (SMA4) except for autosomal dominant inheritance pattern. This presentation is due to the heterozygous mutation in the gene encoding vesicle-associated membrane protein B (VAPB) on chromosome 20q13. The age of onset is in 3rd decade of life and these patients have proximal muscle weakness with lower limb involvement more than upper limbs. This disease is very slowly progressive and most patients remain ambulatory for decades after clinical onset.

Distal spinal muscular atrophy Distal spinal muscular atrophy (DSMA) is inherited as autosomal dominant or recessive fashion and has considerable overlap with hereditary motor neuronopathy (HMN). DSMA is classified into five types and are characterized by distal muscle weakness, wasting, and local areflexia without significant sensory involvement, with or without pes cavus, vocal cord or diaphragmatic involvement. Distal SMA were earlier termed as SMA type 5, but later found to have similar phenotype and genetic mutation as HMN.

Spinal muscular atrophy in general presents with proximal muscle weakness and wasting while the distal SMA behaves like motor neuropathy with distal muscle involvement. The distal form of SMA has a relatively better prognosis and the disease stabilizes in the later stages with patients remaining ambulant and has a normal lifespan except in DSMA1.

Distal spinal muscular atrophy type 1 is also known as spinal muscular atrophy with respiratory distress type 1 (SMARD1) and hereditary motor neuropathy type 6 (HMN6). SMARD1 is a very rare autosomal recessive motor neuron disorder that affects infants and is characterized by diaphragmatic palsy, symmetrical distal muscle weakness, muscle atrophy, peripheral sensory neuropathy, areflexia and autonomic nerve dysfunction. SMARD1 is caused by mutations in the gene for immunoglobulin mu-binding protein 2 (IGHMBP2) located on chromosome 11q13. The disease is fatal with most of the patients requiring ventilatory support and usually dying within the 1st year of life.

DIFFERENTIAL DIAGNOSIS

Congenital muscular dystrophy These children have mental retardation, seizures and dysmorphic facies. They have contractures and grossly elevated serum creatinine phosphokinase (CPK) values with magnetic resonance imaging (MRI) brain showing lissencephaly (cobble stone appearance) or white matter T2W hyperintensity.

Congenital myopathy Dysmorphic facies, ptosis, extraocular muscle paresis and cardiac involvement are seen in these children. Serum CPK and MRI brain is normal.

Congenital myasthenia syndrome These children have fluctuating or persistent weakness of ocular, bulbar, or limb muscles; or arthrogryposis in infancy.

Neonatal myasthenia gravis In 15% of infants born to mothers with autoimmune myasthenia gravis, transient myasthenia occurs in the neonatal period related to transfer of acetylcholine receptor antibodies across the placenta. Affected infants may require respiratory support temporarily and in majority of cases, the symptoms resolve within the 1st month of life.

Congenital myotonic dystrophy Approximately 25% of infants born to mothers with myotonic dystrophy present in infancy. They have facial muscle weakness, inverted V-shaped mouth and myotonia. Examination of mother and positive family history aid in the diagnosis.

Metabolic myopathy like acid maltase deficiency Deficiency of α-1,4-glucosidase patients presents with a severe skeletal myopathy, cardiomyopathy and may have encephalopathy. The diagnosis is confirmed by enzyme assay.

Peripheral neuropathy Charcot-Marie-Tooth disease type 3 (CMT3), or Dejerine-Sottas disease (DSS): DSS is a rare demyelinating neuropathy characterized by delayed motor milestone, proximal weakness, global areflexia and hypertrophied peripheral nerves. The motor nerve conduction velocities are less than 10 m/s which clinches the diagnosis.

Congenital hypomyelinating neuropathy (CHN) CHN is similar to DSS in presentation and some consider CHN to be an extreme form of DSS. Sural nerve biopsies helps to differentiate between these two entities; presence of demyelination/remyelination and an abundance of well-organized onion bulbs favor DSS and only hypomyelination is seen in CHN.

Cerebral hypotonia These children will have features of cerebral involvement like encephalopathy (irritability and poor feeding), seizures and brisk deep tendon reflexes.

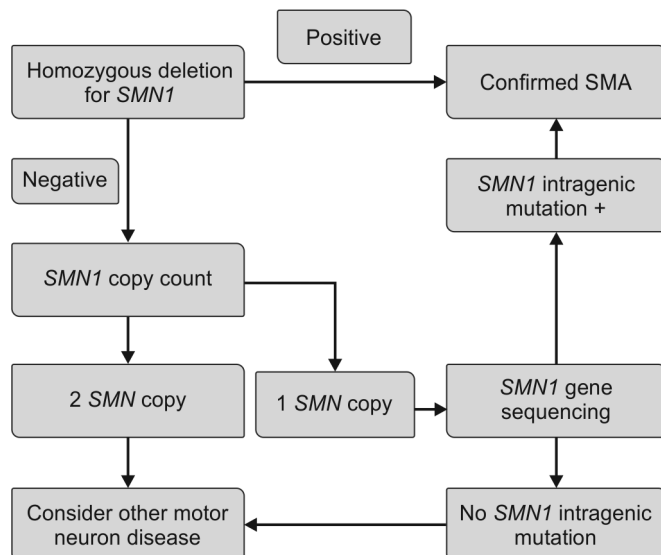
DIAGNOSIS

Molecular diagnosis Homozygous *SMN1* exon 7 deletions as detected by PCR-RFLP (polymerase chain reaction—restriction fragment length polymorphism) is responsible for the disease in 94% of patients with typical SMA. If no homozygous deletion is detected then SMN copy number analysis has to be done and if two SMN copies are present, then alternate diagnosis is considered. If only one *SMN1* copy is present, small intragenic *SMN1* mutations may be responsible for the SMA **(Flow chart 1)**.

Table 2 Variants of SMA not due to *SMN* gene mutation

Variant	Genetics	Age of onset	Clinical features
SMA with congenital arthrogryposis and bone fractures	Xp11.3–q11.2	In utero	• Reduced fetal movements • Contractures and multiple bone fractures • Requires ventilatory support at birth
Spinal muscular atrophy with respiratory distress (SMARD)	Immunoglobulin mu-binding protein 2 (IGHMBP2) AR inheritance	At birth–6 months	• Respiratory distress, cardiomyopathy and lactic acidosis • Distal > proximal muscle weakness
Fazio-Londe disease	AD/AR	Childhood	• Progressive facial and bulbar palsy • Respiratory failure by 2nd decade
Brown-Vialetto-Van-Laere syndrome	Mutation in Riboflavin transporter gene	Before 18 years	• Similar to Fazio-Londe but has associated sensorineural hearing loss • Treatable with riboflavin supplementation
Kennedy's disease (X-linked recessive bulbospinal neuronopathy)	X-linked recessive CAG trinucleotide repeat sequence at androgen receptor	After 30 years	• Bulbar involvement with proximal muscle weakness, wasting and fasciculations • Gynecomastia and testicular atrophy may be present

Abbreviations: AR, autosomal recessive; AD, autosomal dominant.

Flow chart 1 Approach to genetic analysis of SMA


Note: If SMA is suspected, genetic analysis (homozygous deletion of *SMN1* gene) will confirm the entity and no further investigations are required. If no homozygous deletion is detected, *SMN1* copy number is ascertained and if two copies are found an alternate diagnosis is considered. If only single *SMN1* copy is present then *SMN* gene sequencing is done to rule out any intragenic mutations. If single *SMN1* copy shows intragenic mutations then SMA is confirmed and if absent then alternate diagnosis is considered. *Abbreviations:* SMA, spinal muscular atrophy; SMN, survival of motor neuron; +, present

Nerve conduction study (NCS) and electromyography (EMG) The motor NCS may be normal or the compound muscle action potential may be reduced. The sensory NCS is normal. EMG shows features of denervation like fibrillation potentials, positive waves and fasciculations. Motor unit action potentials are of large amplitude, long duration, polyphasics with reduced recruitment (neurogenic pattern).

Muscle biopsy Muscle biopsy is pursued if the genetic analysis is negative and if primary muscle disease is suspected after NCS-EMG. The muscle biopsy in SMA shows evidence of denervation atrophy. The features of denervation atrophy are as follows: Group fascicular atrophy **(Fig. 2)**; small angular atrophic muscle fibers; fiber type grouping, i.e., areas with either muscle fiber type 1 or type 2 only which is due to chronic reinnervation.
Figure 2 Hematoxylin and Eosin stain of muscle biopsy at 200X of SMA1: Group atrophy along with small angulated fibers

Serum creatinine phosphokinase (CPK) CPK is normal or 2–4 times elevated.

CLINICAL MANAGEMENT

Spinal muscular atrophy is a genetic disease for which no cure is available at present and only supportive management can be offered **(Table 3)**. Nevertheless, animal and human trials are ongoing for the identification of a cure for this fatal disease.

Family Education and Counseling

During the first meeting with parents, it is important to explain the disease process, pathogenesis, and the patient's prognosis. Other important genetic topics including sibling recurrence risk, carrier testing and information that may help with family planning (prenatal diagnosis) should be discussed with the parents. The physician should also formulate a plan of multidisciplinary intervention with the family.

Genetic Counseling

Spinal muscular atrophy has autosomal recessive inheritance pattern and the carrier state of *SMN1* gene deletion in the population is high. If a child is affected, the chance of next sibling getting affected is 25%. Proper genetic counseling should be offered to the parents and the relatives and carrier testing should be done. A prenatal diagnosis in the subsequent pregnancy is also advised.

Pulmonary Care

The key respiratory problems in SMA include impaired cough resulting in poor clearance of lower airway secretions; hypoventilation during sleep; chest wall and lung underdevelopment; recurrent aspiration and pneumonia and scoliosis. Pulmonary disease is the major cause of morbidity and

Table 3 Consensus statement for standard of care in spinal muscular atrophy

Complications	Monitor	Management
Pulmonary care		
Respiratory failure	• Arterial blood gas analysis • Chest X-ray • Oxygen saturation	• Noninvasive ventilation • Invasive ventilation if required and needs detailed discussion with the parents
Impaired cough		• Manual assisted coughing • Cough assist devices
Pooling of secretions		• Frequent suctions, chest physiotherapy and prevention of aspiration
Aspiration pneumonia	Total count and chest X-ray	• Antibiotics
Prevention of respiratory infections		• Influenza and pneumococcal vaccines
Nutritional support and hydration	Body weight	• Feeding tubes • Dietician opinion for a adequate diet • Gastrostomy/jejunostomy
Speech	Speech assessment	• Speech therapy
Neurorehabilitation		• Physical therapy • Occupational therapy • Prevention of contractures • Prevention of osteopenia and fractures
Scoliosis		• Corrected surgery • Spinal brace
Orthoses		• Walkers • Limb orthoses

mortality in SMA1 and SMA2 and may occur in a small proportion of patients with SMA3. Respiratory assessment includes evaluation of cough effectiveness, observation of breathing and monitoring gas exchange. Ventilatory support should be added at night if sleep-disordered breathing is present and cough assistance provided if cough efficiency is reduced. Polysomnography is useful even in children without obvious symptoms, and can be used to initiate and titrate respiratory support. Swallowing evaluation is indicated in cases of acute unexplained respiratory deterioration and recurring pneumonia.

Airway clearance Caregivers of these patients should learn to assist coughing in all patients with ineffective cough. These can be done manually or with mechanical cough assisted devices (mechanical insufflation-exsufflation). Daily assisted cough is recommended in more severely affected patients. Secretion mobilization techniques include chest physiotherapy, postural drainage and oral suctioning can assist in removing secretions.

Respiratory support In patients with daytime hypercapnia, respiratory support is clearly indicated. In children with sleep-disordered breathing, nocturnal noninvasive ventilation reduces symptoms of sleep disturbance, nocturnal sweating and improves quality of life. Noninvasive ventilation settings are individualized to achieve adequate inspiratory chest wall expansion, air entry and normalization of oxygen saturation. Noninvasive ventilation should be combined with airway clearance techniques. In nonsitters the option of tracheostomy and mechanical ventilation needs to be discussed with parents in consideration with the child's quality of life.

Nutritional Care

The main gastrointestinal and nutritional complications in SMA are: feeding and swallowing problem due to bulbar dysfunction; gastrointestinal dysfunction like constipation, delayed gastric emptying and gastroesophageal reflux and weight-related problems as the nonsitters have growth failure and excessive weight gain is a problem with sitters and walkers.

When delayed gastric emptying or diminished motility is present, prokinetic agents like metoclopramide or domperidone is useful. Short-term courses of H_2 receptor blockers (e.g., Ranitidine) and proton pump inhibitors (e.g., omeprazole and pantoprazole) can be given if chest discomfort is present. Placement of percutaneous gastrostomy tube is advised when significant bulbar dysfunction is present but it does not prevent aspiration. In some children with severe gastroesophageal reflux Nissen fundoplication can be done.

Supportive Management

Children with SMA should be provided routine vaccinations, appropriate nutritional support orally or via a feeding tube and proper hydration. Pneumococcal pentavalent vaccines as well as influenza vaccines are advised to prevent respiratory tract infection in these patients.

Orthopedic care and rehabilitation The key problems in rehabilitation are contracture formation, spinal deformity, skeletal pain, osteopenia and fractures. Physiotherapy includes stretching, nonfatiguing active range of motion exercise, and especially aqua therapy to improve the endurance of muscles and prevent contractures. Upright weight bearing and ambulation is also encouraged.

Occupational therapy Occupational therapist plays an important role in improving the functional skills of the disabled patient. In children with limited hand function, adaptive devices are available for power mobility control. Home modifications should be made for safe accessibility and optimal independence.

Goals of therapy and surgery depend on functional level of the child and the family's wishes. Appropriate sitting posture should be maintained and walking should be encouraged with assistive devices and orthotics. Spinal orthoses may provide postural support but do not prevent progression of scoliosis. Scoliosis surgery appears to benefit patients who survive beyond 2 years of age when curves are severe and progressive and should be performed while pulmonary function is adequate.

Newer Therapeutic Strategies

Neuroprotective strategies Several agents were used as neuroprotective drugs to rescue motor neurons; Riluzole a glutamate antagonist, creatine to improve energy metabolism, and albuterol for its anabolic properties and the molecular effect on *SMN2* gene expression has been studied without much success.

Antisense oligonucleotides (ASOs) Synthetic ASOs bind to *SMN2* derived transcripts and promote exon 7 inclusion during splicing which has resulted in increase in SMN protein levels in cell-based models.

Histone deacetylase inhibitors (HDAC) Control of the acetylation state of histones is one of several epigenetic mechanisms that regulate gene expression. Sodium butyrate was shown to increase full-length *SMN2* transcript levels and protein levels in cell lines derived from SMA patients. The half-life of this compound made it an unlikely candidate for human trials. Other HDAC inhibitors like phenyl butyrate, hydroxyurea and valproic acid are also being explored.

Gene therapy Adeno-associated virus has been used to replace *SMN1* gene in mouse models. Technical difficulties with respect to efficient gene delivery to spinal cord motor neurons and limitations in human gene therapy necessitate further studies in this area.

Stem cell therapy The use of stem cells to help maintain or restore vulnerable motor neuron populations has been explored. It is a promising endeavor as proved by an animal study with differentiated embryonic stem cells transplanted into the spinal cord of rats with motor neuron injury which resulted in the successful reinnervation of lower extremity muscles.

IN A NUTSHELL

1. Spinal muscular atrophy is an autosomal recessive disease due to homozygous deletion of *SMN1* gene in chromosome 5q.
2. Spinal muscular atrophy is due to degeneration of anterior horn cells of spinal cord with or without cranial motor nuclei.
3. Spinal muscular atrophy has been classified into four types by International consortium of SMA based on age of onset and highest function achieved. SMA0 manifests in utero as decreased fetal movement and has respiratory failure at birth. SMA1 present as floppy infant while delayed motor milestones is the presenting feature in SMA2. A limb-girdle pattern of weakness with wasting, fasciculation and areflexia is observed in SMA3 and SMA4.
4. The characteristic feature is normal intelligence, sparing of ocular and facial muscles.
5. Prognosis is grim in SMA0 and SMA1 while SMA3 and SMA4 remain ambulatory with or without support.
6. Mortality is mainly due to respiratory failure and aspiration pneumonia.
7. Spinal muscular atrophy is diagnosed clinically and confirmed by genetic analysis.
8. In SMA variants, electrophysiology and histopathology is largely relied upon for diagnosis.
9. Once the diagnosis is established parental counseling and family education is given regarding the genetics of the disease and prognosis.
10. No cure has been identified so far for SMA.

Chapter 43.6
Muscular Dystrophies

Satish V Khadilkar, Rakhil S Yadav

Muscular dystrophies are inherited progressive disorders of muscles usually caused by defects in cytoskeletal proteins or enzymes, leading to degeneration and regeneration of muscle fibers and resultant replacement by adipose and fibrous tissues. Muscular dystrophies lead to inexorably progressive muscular weakness and resultant chronic disability.

A wide variety of genetic defects lead to dystrophies. The initial clinical classifications of dystrophies took the base of clinical features like age at onset and phenotypic characteristics, along with the Mendelian genetics. **Table 1** shows one such basic approach to categorizing dystrophies. In the recent years the field has seen remarkable advancements. The emergence of investigative techniques like histopathology, enzyme histochemistry, immunocytochemistry and electron microscopy studies have greatly increase our understanding of the pathophysiology of muscular dystrophies at the cellular and molecular levels. The next leap has been molecular genetics. With advent of molecular genetics, we are able to diagnose muscular dystrophies with accuracy and have developed further understanding of the process of dystrophies. These advances have led to accurate diagnosis, antenatal diagnosis and genetic counseling, and to an extent, prevention of these progressively disabling conditions. While these advances have not yet translated into definable therapies for the sufferers, we are knocking at the doors with newer treatment. It would appear that coming times will see effective therapies for these diseases.

DUCHENNE MUSCULAR DYSTROPHY/BECKER MUSCULAR DYSTROPHY

This is the most frequent and best studied early onset muscular dystrophy. It was described as pseudohypertrophic muscular dystrophy by Gaetano Conte (1836) and Meryon (1851). It was named after Duchenne who described it in 1868.

Epidemiology

Duchenne muscular dystrophy (DMD) begins in early childhood and runs a relatively rapid, progressive course. The incidence is about 1 in 3,500 live male birth. Being an X-linked recessive trait, it is seen almost exclusively in males. But manifesting females have been documented **(Box 1)**. DMD occurs in all communities in India. Due to prevalent religious concepts and illiteracy, more than one case of dystrophinopathy in a family continues to be seen in India.

Table 1 Classification of muscular dystrophy based on mode of inheritance

X linked	Autosomal recessive	Autosomal dominant
DMD	LGMD 2 (A-O)	LGMD 1 (A-E)
BMD	MDC	MDC (Ullrich/Bethlem)
EMD	Distal myopathy (Nonaka, Miyoshi)	Distal myopathy (Walender, Udd, Laing, Markesbery-Griggs)
		FSHD

Abbreviations: DMD, Duchenne muscular dystrophy; BMD, Becker muscular dystrophy; LGMD, limb-girdle muscular dystrophy; MDC, congenital muscular dystrophy; EMD, Emery-Dreifuss muscular dystrophy; FSHD, facioscapulohumeral dystrophy.

BOX 1 DMD manifestation in female

When female patients manifest the disease, they may have only one X chromosome, as occurs in the Turner syndrome (XO), and that chromosome carries the Duchenne gene, or the Lyon principle may be operative, i.e., there is inactivation of the unaffected paternal X chromosome allowing expression of the mutated Duchenne protein from the maternal chromosome in large proportion of embryonic cells.

Etiology

Mutation on short arm of X-chromosome at Xp21 leads to DMD. It is one of the largest genes, spanning 2.5 MB (0.1% of total genome). It consists of 79 exons (0.6% of total gene) and codes for a 14kb mRNA. The gene product is dystrophin, a 428 kd protein. It is expressed in the skeletal, cardiac and smooth muscles of the body and also in the brain. The rate of spontaneous mutations is high in this large gene. Deletion or duplication of gene segments is seen in two-third of patients. Deletions are seen at two *hot spots*. Most common deleted region is between exons 43 and 52 followed by that between exons 2 and 21. Duplications are less common than deletions and further smaller number of patients has point mutations, which require elaborate and expensive genetic testing. Mutation in the DMD gene results in loss of function of dystrophin.

Koenig proposed *The reading frame rule* to explain the molecular basis of two allelic forms of muscular dystrophies DMD/ Becker muscular dystrophy (BMD). 90% of cases of DMD and BMD follow the reading frame rule. Out of frame deletions lead to DMD while in frame deletions lead to BMD **(Fig. 1)**. In the minority of patients who do not follow the frame shift rule, milder clinical phenotypes are seen particularly in exons 3 to 7.

Pathogenesis

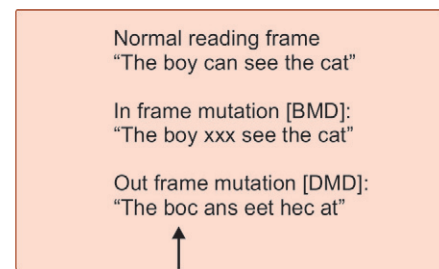
Dystrophin is located subsarcolemally and is a cytoskeletal protein **(Fig. 2)**. Absence of dystrophin leads to delocalization of


Figure 1 Reading frame rule in DMD/BMD
Figure 2 Dystrophin-Glycoprotein complex
Source: Dr Renuka Yadav.

dystrophin associated proteins from the membrane, disruption of the cytoskeleton with resultant membrane instability and increased susceptibility to mechanical stress. In addition, altered membrane permeability and abnormal calcium homeostasis are thought to play a role, with increased cytosolic calcium concentration leading to activation of proteases such as calpains. The absence of nitric oxide synthase, delocalized from the subsarcolemmal membrane, may contribute to dystrophic features, in indirect ways. Commonly studied animal model of DMD is mdx mouse, carrying a nonsense mutation in exon 23.

Clinical Features

Presenting Features

The most frequent presenting symptoms are motor delay or an abnormal gait. Affected boys present with difficulty in running or getting up from the ground, frequent falls, or toe-walking. Most present between 3–5 years. Less frequent presentations include language or global developmental delay, or incidentally raised serum Creatine kinase or transaminase level when these investigations are performed for other reasons.

At birth, children usually do not have any symptoms. Only occasionally, delay of motor milestones may be seen. Mothers notice clumsiness of gait which is initially taken as normal, but it persists. The problem soon becomes more clear as children begin seeking support while getting up from the ground and rise with support of one hand on the knee, the Gower's maneuver **(Figs 3A to E)**. At this stage, calf hypertrophy begins.

At 2–3 years of age, running becomes different and children cannot jump with both feet off the ground. Tightness begins at tendoachillis and may be seen in other lower limb joints as well. By 5 or 6 years of age, further weakness is noted and children have more difficulty in rising from chair and climbing stairs.

It is important to note that the natural growth spurt is at its best *between 2–6 years* of life and tends to offset the progressive muscular weakness resulting from the dystrophy. Hence, some parents report motor task improvement in children at this stage. This apparent improvement seen in some children declines as age advances.

By the age of 6 or 7 years, the weakness becomes more evident. As paraspinal muscles weaken, lordosis develops and abdomen is seen to be protuberant. Waddle develops due to the weakness of gluteal muscles, in particular, gluteus medius **(Box 2)**. At this stage, the quadriceps is often weakened, leading to episodes of knee buckling and falls which are spontaneous or result from small pushes and on uneven grounds.

BOX 2 Mechanism of waddling gait

Gluteus medius spans from iliac crest to the greater trochanter. In normal individuals, when one leg is raised off the ground, opposite gluteus medius contracts, keeping both anterior superior iliac spines at same level. With a weakened medius, pelvis tilts to the side of the raised leg, this alternates as child walks, resulting in waddle.

As the condition advances, extensors of the knee and hip joints become further weak and children find it more difficult to stand

Figures 3A to E Gower's sign

on their own and gradually take to the wheel chair. This stage is reached between 9–12 years, ambulatory being maintained longer in those who are on physiotherapy programs and use orthoses.

Contractures are seen in many muscles. In the initial stages, they are seen in the tendoachillis and the ilio-tibial bands. When the child becomes wheelchair hound, they become more pronounced and affect the knee and the hip areas. This makes it further difficult for the child to find a restful position for sleep and children sleep with knees bent, tilted to a side. The spinal deformities also increase, kyphoscoliosis adds to the problems of respiratory dysfunction.

On Examination

Hypertrophy Muscle hypertrophy is seen most prominent in the calves, but many other muscles like deltoids, brachioradialis, infraspinatus, glutii, temporalis and tongue are enlarged in size. The enlarged muscles are rubbery in consistency. As the disease advances, hypertrophy becomes less evident and the above-mentioned muscles reduce in size. Gastrocnemius and deltoid muscles often continue to remain large till late in the disease. In an occasional patient, no hypertrophy is seen.

Weakness Weakness of the muscles initially involves the lower limbs. It begins in the quadriceps and gluteal musculature and then tibialis anterior is weakened, resulting in foot drop. At this stage, children begin to walk on toes. Upper girdle weakness follows and is seen in serreti, lower part of pectorals, latissimus dorsi, biceps, and brachioradialis muscles. Weakness of the serratus anterior, lower trapezius and rhomboids causes winging of scapulae. The ocular, facial, bulbar and hand muscles are usually spared.

Because of simultaneous hypertrophy of deltoid superolaterally, infraspinatus inferomedially and wasting of posterior axillary fold, the appearance looks like valley (valley sign). It is best seen while arm abducted to 90° (or best possible abduction if 90° abduction is not possible) and hand facing upward, examiner observing the posterior shoulder girdle **(Fig. 4)**.

Reflexes Deep tendon reflexes are depressed in weak muscles and ankle reflex continues to be elicited till very late in the disease.

Cardiac findings Cardiac muscle is also involved in DMD leading the hypocontractility, dilated cardiomyopathy. Cardiac involvement starts early and subclinical disease is seen in one-fourth of patients under 6 years of age. Overt cardiac symptoms begin after 10 years of age, one-third of patients are symptomatic by 14 years and it is present in all patients over 18 years of age. Cardiac conduction defects are less commonly seen.

Figure 4 Valley sign

Respiratory involvement Restrictive lung disease is common. Vital capacity begins to diminish around 10 years of age, reducing at the rate of 10%/year approximately. As the vital capacity goes below 1 liter, the complication rates increase. Obstructive sleep apnea is seen in DMD children as early as the 1st decade and as vital capacity decreases further in the 2nd decade, children hypoventilate. Sleep disturbances due to both the respiratory changes are commonly encountered.

Intelligence The average intelligence of DMD tends to be lower and patients tend to have lower values of the verbal IQ. Attention deficit disorders may also be seen in minority of patients.

Orthopedic complications Scoliosis, long bone fractures due to falls, osteoporosis.

Malignant hyperthermia No clear association. But increased risk if exposed to halothane or succinylcholine.

Becker Muscular Dystrophy

This is a milder clinical form of dystrophinopathies. The onset is much later, mean age 12 years (range 5–45 years). Patients usually walk well into adult life. The weakness follows the pattern of DMD and cardiac involvement is less frequent.

Examination of the mothers of affected boys The majority are asymptomatic. However, a minority of carriers have clinically evident muscle weakness; the manifesting carriers. Some carriers experience muscle pains or cramps without weakness. Cardiac involvement is usually subclinical, but an occasional carrier may have severe cardiac failure. It is believed that carriers do not have reduced life expectancy.

Other phenotypes associated with dystrophinopathies (1) Exercise intolerance; (2) Myalgia; (3) Exertional myoglobinuria; (4) Isolated cardiomyopathy; and (5) Asymptomatic hyperCKemia. In general, familial cases with DMD seem to follow similar clinical courses but on occasions, striking intrafamilial phenotypic variability has been seen. Intrafamilial variation with same in-frame mutation is reported. Approximately 30% of patients have no family history of the disease and these represent spontaneous mutations.

Approach to Diagnosis

First, determine the phenotype of the index case; examine the family members and estimate serum muscle enzymes. Serum CK levels are markedly elevated in patients with DMD. The elevations are often extreme, being in thousands. The CK is elevated at birth and tends to rise by 3 years of age. They progressively decrease as the child gets weaker and the muscle mass is lost. Serum glutamic-oxaloacetic transaminase (SGOT) and serum glutamic-pyruvic transaminase (SGPT) levels are also increased commensurate with the CK elevation. This is important to recognize, as often children are unnecessarily investigated for hepatic dysfunction.

Molecular genetic testing Genetic studies are important for accurate diagnosis, genetic counseling and prenatal diagnosis. Multiplex polymerase chain reaction (PCR) has been used to study the *dystrophin* gene. PCR techniques study 19–32 exons covering the hot spots. These tests are able to detect the common deletions. Multiplex ligation dependent probe amplification (MLPA) is a more sensitive technique for detecting deletions. MLPA test studies all the 79 exon as and is able to detect duplications as well, increasing the yield by about 10%. If MLPA testing is negative, the DMD gene can be tested for point mutations. However, direct sequence analysis of the DMD gene is not widely available and exorbitantly expensive. Previously unidentified deep intronic mutations have recently been identified by a targeted high-density oligonucleotide microarray technique.

In India, multiplex PCR is regularly used in many centers in the research and service sectors while MLPA is available in fewer set-ups. Carrier detection requires the MLPA test, as it studies the dosing effect. Prenatal genetic diagnosis requires chorionic villus sampling and is available in India.

Electrodiagnosis Nerve conduction studies (NCV) are normal in early DMD. Only in advanced disease, the compound muscle action potentials (CMAP) may tend to decrease in amplitude. Needle EMGs confirm the myopathies nature of the illness by showing short duration, low-amplitude polyphasic motor unit potentials, particularly in proximal muscles **(Fig. 5)**. Some children have increased spontaneous activity which is believed to be due to reinnervation. As muscle mass reduces with advancement of the disease, motor units become progressively smaller and silent in some areas. Electrodiagnosis should be scheduled after collection of blood for CK level, as CK rises after needling of muscles. Also, it is preferable to avoid needle tests on muscles on which biopsy is planned.

Muscle biopsy Indication of biopsy in recent years is limited to situations where in clinical phenotype is atypical or genetic test is negative. Muscle with MRC grade 3–4 power should be selected for biopsy. The muscle tissue should be snap frozen in chilled isopentane to preserve the enzymes. Light microscopy shows degenerating necrotic muscle fibers with invasion of macrophages, as well as clusters of regenerating muscle fibers which have basophilic cytoplasm **(Fig. 6)**. Increased variability of muscle fiber size is common; fibers are initially larger than normal and become smaller later on. Histochemistry with ATPase shows type 1 fiber predominance. In advance stages, significant replacement of fibers by fat and endomysial connective tissue is seen. Immunostaining confirms absence of dystrophin **(Fig. 7)**. Three antibodies (Dys 1,

Figure 6 Muscle biopsy H & E stain: fiber size variation, myophagocytosis and regenerating fibers are seen

2 and 3) are available against dystrophin. They cover the carboxy terminus, central region and amino terminus. As each antibody covers only a portion of the protein, all three should be preferably used. In dystrophin deficiency as seen in BMD, the protein staining is irregular and fragmented.

Carrier females CK level are raised in half of known carriers. MLPA can detect the carrier status.

Management

General Management and Surveillance *(Table 2)*
In India, schools are not uniformly sensitized to the needs of DMD children and issues arising out of the special motor requirements of the child need to be individually addressed. Parental overprotection is common and many children do not attend school, resorting to tuitions at home. Behavior difficulties are common with DMD children and counseling of the whole family unit can be beneficial.

Corticosteroid Therapy
Proposed mechanisms Alteration of regulation of genes in muscle fibers, slowing of the rate of skeletal muscle breakdown, reducing

Figure 5 EMG showing myopathic discharges
Source: Dr Khushnuma Mansukhani, Department of Electrophysiology, Bombay Hospital Institute of Medical Sciences, Mumbai.
Figure 7 Normal immunostaining for Dystrophin 1. Note the brown staining of the sarcolemma (The muscle membrane does not take-up the stain in dystrophin deficiency)

Table 2 General management and surveillance in DMD

Cardiac	• Surveillance after 10 years of age • Annual ECG, 2D ECHO; Holter (if rhythm disturbance present) • ACEI, beta blocker
Respiratory	• Surveillance before ambulation lost—annually; afterward—frequently • Polysomnography • Early management of respiratory infection • Vaccination—influenza, pneumococci • NIPPV—Noninvasive positive pressure ventilation • Ventilatory support
Scoliosis	• Surveillance after 5 years of age • Surgery if degree of scoliosis is > 25% and vital capacity > 30% of predicted • Calcium and vitamin D supplement
Contracture	• Exercise program • Tendon release surgery

Figure 8 Exon skipping in DMD

cytotoxic T-cells, lowering cytosolic calcium concentrations and increasing myogenic repair.

Optimum dose Prednisolone/Prednisone: 0.75 mg/kg/day (Lower dose 0.3 mg/kg/day result in lesser degree of benefit and higher dose 1.5 mg/kg/day do not result in additional benefits).

Dosing regimens 1.25 mg/kg and 2.5 mg/kg alternate day doses; 10 days on and 10 days off; 10 days on and 20 days off; followed by 5 mg/kg/dose twice weekly. *Deflazacort*: 0.9 mg/kg/day is another option.

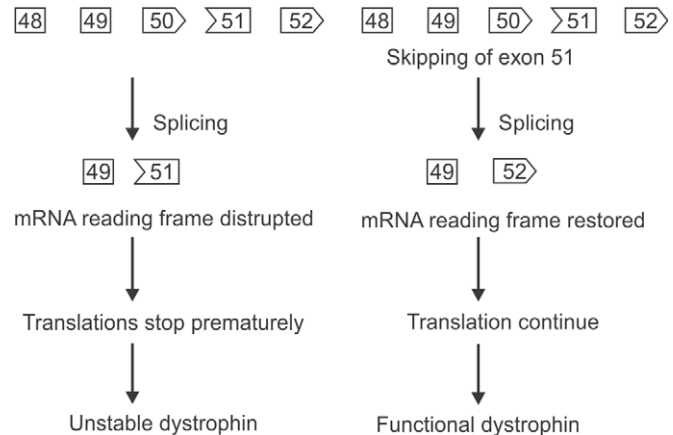
It is generally believed that corticosteroid treatment should be started early in the course of the disease but the optimal duration of the therapy is unclear. Trials show improved muscle strength within 10 days, which is maximal at 3 months and is maintained up to 18 months. Side effects of corticosteroids should be monitored and treated timely. Prednisolone and deflazacort have similar efficacy but different side effect profiles. FOR-DMD trial is expected to gives us clear idea about dose optimization and therapeutic window of prednisolone versus deflazacort. In India, where prevalence of tuberculosis is high, corticosteroid treatment may flair up underlying tuberculosis.

Drugs like oxandrolone, azathioprine, cyclosporine, creatine monohydrate, nifedipine, leucine, selenium and vitamin E, and antiserotonergic drugs methysergide and pizotifen have been tried in research settings, without robust evidence towards benefit.

Gene Therapy

Viral vectors The *DMD* gene is very large and, hence, it is difficult to have a viral vector to carry the entire gene. Critical fragments of the gene can be carried by adeno associated viral vectors. Such microdystrophin and minidystrophin genes have been injected in mice and dystrophin has been successfully expressed. How to provide the gene to multiple muscles groups is an issue as is the potential downsides of persistent immunomodulation amongst the recipients.

Antisense oligonucleotide exon skipping (Fig. 8) This technique can be used to redirect splicing which induces exon skipping and thus helps production of the functioning dystrophin. However, the antisense oligonucleotide has to be tailored to the deletion which is a limitation. Providing sustained therapy is another unanswered issue.

Read through stop codon strategies Gentamicin and PTC 124 have been studied. Gentamicin have not been successful in clinical


trials. PTC 124 is under trial. A possibility of global read through is a potential a risk of this therapy.

Stem cell therapy Myoblast transfer and bone marrow derived stem cell transfer has been used in research settings. Mesenchymal stem cell sources presently appear most promising.

Box 3 shows an approach to patient with DMD.

Outcome
Death is usually the result of pulmonary infections and respiratory failure and sometimes, of cardiac decompensation.

Prevention
The most relevant part of the genetic advances is the ability to prevent the further occurrence of the disease in families. Hence, all families having a DMD patient should be referred for genetic counseling. Detection and counseling of female carrier is an important step in the preventive management. Prenatal diagnosis should be pursued for carrier mothers, and is most helpful when deletion is detected in the index case. Chorionic villus sample is tested for the DMD gene at 10–12 weeks of gestation and affected conception is medically terminated. It is important to remember that germline mosaicism can go undetected when the carrier testing is performed. When mosaicism exists, the risk for future pregnancies is considered to be approximately 10–20%.

BOX 3 Approach to Duchenne muscular dystrophy

Clinical
• Male child
• Childhood onset progressive proximal muscle weakness [Gower's sign]
• Pseudohypertrophy of muscles especially calf
• Normal birth history
• Contributory family history

Investigation
• Serum creatine kinase
• EDX [particularly if inconclusive CK level]
• Molecular genetic testing
• Muscle biopsy with immunostain for dystrophin [if genetic testing is not available or informative]

Management
• General supportive care
• Corticosteroids
• Gene therapy

EMERY-DREIFUSS MUSCULAR DYSTROPHY

This muscular dystrophy is relatively benign X-linked recessive dystrophy characterized by contractures. Gene is located on *Xq28*, encode for the protein, Emerin, which is a protein on the nuclear membrane. Emerin plays a role in the attachment of nuclear membrane to heterochromatin.

Clinical Features

Age of onset varies from childhood to late adolescence or adulthood. Weakness initially affects the upper arm and pectoral girdle musculature and later the pelvic girdle and the distal muscles in the lower extremities. Early appearance of contractures in the flexors of the elbow, extensors of the neck, paraspinal muscles and achillis tendon is an important diagnostic clue.

On examination, during movement the contractures may feel almost bony, rather than a tight tendon. Occasionally facial muscles are affected. There is no hypertrophy or pseudohypertrophy. Mentation is unaffected. Cardiac conduction defects are common accompaniments. Female carriers are known to develop cardiac conduction defects, much later than patients.

Management

Diagnosis Strong clinical suspicion followed by DNA studies confirms the diagnosis. Emerin is expressed in skin as well and hence skin biopsy can be used for the diagnosis in place of muscle. CK levels may be elevated. Muscle biopsy and EMG favor myopathy.

Treatment There is no cure. Management is supportive. Cardiac abnormalities require monitoring. Atrial blocks can manifest suddenly and be fatal, hence pacemaker should be considered early in the disease. Female carriers need screening with ECG in 3rd decade and later.

Sporadic and autosomal dominant forms are also known with similar presentations, due to defect in lamin or nesprin. Half of the cases have none of known mutations, making understanding of this syndrome more complex.

CONGENITAL MUSCULAR DYSTROPHY

Congenital muscular dystrophies (CMD or MDC) have autosomal recessive inheritance. They announce themselves at birth with hypotonia and severe weakness **(Fig. 9)**. Intellectual disability may be present. Joint contractures are prominent, particularly at large joints of the lower limbs. MRI brain shows white matter signals **(Fig. 10)**. **Table 3** describes salient features of individual CMD. These are discussed in detail in next Chapter 43.7. Merosinopathy and Fukuyama muscular dystrophies are briefly described here.

MDC 1A: Merosinopathy

Laminin α2 (merosin) is a family of glycosylated proteins located in basement membrane. It is made of three chains: α2, β1, and γ1 and attaches to the dystroglycan complex. It is present in muscle, skin and peripheral nerves.

Figure 9 Merosinopathy. Note the anterior axillary fold suggesting pectorlis weakness

Rigid spine syndrome	AR	1p35–36	Selenoprotein N1	Normal or slightly elevated	
Ullrich/Bethlem	AR/AD	21q22.3; 2q37	Collegens 6A1, 6A2, 6A3	Normal or slightly elevated	

Abbreviations: CMD/MDC, Congenital muscular dystrophy; LGMD, limb-girdle muscular dystrophy; WWS, Walker-Walberg syndrome; MEB, muscle eye brain disease.

Clinical features Patients present with severe weakness of the trunk and limbs and hypotonia at birth. Extraocular muscles are usually spared. Prominent contractures of the feet and hips are present. Intelligence is often normal. One-fifth of patients have epilepsy. Milder form with delayed onset of symptoms and mild weakness is known.

Management Skin or muscle biopsy reveals merosin deficiency. The final diagnosis depends on genetic confirmation because merosin reduction can also be a secondary phenomenon. Patients with merosinopathy often remain weak, have reduced quality of life and need external help and care.

Fukuyama Muscular Dystrophy

Fukutin is an enzyme associated with the golgi complex that takes part in glycosylation. Mutation leads to severe CNS manifestations associated with Fukuyama type muscular dystrophy because glycoprotein-dystrophin complex is expressed in the CNS and muscles.

Clinical features Children are usually normal at birth. Joint contractures affecting multiple large joints develop after few months. Such children are weak and may not be able to walk. They are also severely retarded and speech does not develop well in many children. Dependent existence is the norm.

Diagnosis Muscle biopsy shows changes of finer size variation, internal nucleation, increased fibrosis and presence of inflammatory cells. In a minority of patients, features of neurogenic changes may be seen in some areas. MRI scans confirm widespread white matter changes, more prominent in the anterior areas. Other brain malformations like malformations of the gyri have been shown on postmortem examinations.

Combination of muscular dystrophy, lissencephaly, cerebellar malformations, severe retinal and eye malformations are seen in Walker-Walberg syndrome (WWS) and muscle eye brain (MEB) disease. WWS is more severe form than MEB.

MYOTONIC DISORDERS

- Myotonic dystrophies: DM1, DM2, DM3
- Nondystrophic myotonias:
  - *Sodium channel*: Paramyotonia congenita, potassium sensitive, hyperkalemic periodic paralysis
  - *Chloride channel*: Becker (AR), Thomsen (AD).

Myotonic Dystrophy Type 1

Myotonic dystrophy type 1 (DM1) is characterized by muscle weakness, myotonia and systemic abnormalities like baldness, early cataracts, gynecomastia, etc. It is an autosomal dominant disease and the mutations are seen in myotonic dystrophy protein kinase (*DMPK*) gene, located on chromosome 19q13.3. It is a triplet repeat disorder (CTG). Normal individuals have between 5 and 30 repeats while patients have expansions going beyond 100. Disease severity correlates with the number of repeats. It is also important to realize that different body tissues have different repeat numbers and hence are affected with variable severities. Hence, it is not safe to prognosticate on the number of repeats in the peripheral blood. Anticipation is common in DM1 and maternal transmissions usually result in severe presentations.

Clinical Features

The illness usually begins in 2nd decade of life. The presenting weakness can be distal, leading to diagnostic difficulties. Patients have low set ears, open mouth, long face, temporal hollowing and wasting and weakness of sternocleidomastoid muscles **(Figs 11A and B)**. Shoulder and hip girdles are weak and gastrocnemius and hamstrings are often uninvolved. Ptosis and external ocular

Figures 11A and B Myotonic dystrophy: (A) Swan neck; (B) Hatchet face

movement paresis is seen in some individuals and palatal weakness leads to change in voice. As the muscles get weaker, myotonia becomes less prominent and may eventually be lost.

The child often becomes accustomed to the myotonia and does not complain about it and examiner has to ask leading questions like difficulty in relaxation of hand grip, to elicit the history. The demonstration of myotonia is done either by percussion of the muscle with a reflex hammer or after firm voluntary contraction. Examiner looks for difficulty in relaxation of the muscle after sustained contraction or a sharp tap. Percussion myotonia can be checked by percussion of the thenar eminence or of posterior muscles of forearm.

Systemic manifestations Mild to moderate mental retardation, cardiac conduction disturbances and tachyarrhythmias, excessive day time somnolence, enhanced sensitivity to barbiturates and morphine, premature cataracts having Christmas tree like appearance and endocrine abnormalities of thyroid, pancreas, hypothalamus and gonads are all seen in varying severities in patients of DM1.

Management

Definitive diagnosis is achieved by DNA analysis. EMG study elicits a characteristic sound called dive bomber or motorcycle potentials **(Fig. 12)**. Muscle enzymes are often abnormal. Drugs to treat myotonia include quinine, phenytoin, procainamide, mexiletine and acetazolamide. Supportive treatment consists of ankle foot orthoses for foot drop, wrist splints; modafinil for hypersomnolence and screening of family members.

Congenital Myotonic Dystrophy

This is seen in children of myotonic mothers. Cardinal features are hypotonia, facial paralysis, failure to thrive, feeding difficulties and mental retardation. Repeated respiratory infections are encountered. Poor fetal movements and polyhydramnios indicate that symptoms begin in intrauterine life. Severe weakness of face, jaw and elevated diaphragm with thin ribs on a chest X-ray provide a clue to the diagnosis. Congenital DM is almost always due to large unstable CTG repeat expansions occurring during maternal transmission. Examination of the mother with milder clinical features of DM confirms the diagnosis.

Limb-Girdle Muscular Dystrophies

Autosomal dominant limb-girdle muscular dystrophies (LGMDs) are termed type 1 while recessives form type 2. As a group, LGMDs present in 2nd or 3rd decades of life but some forms can be seen
Figure 12 EMG showing myotonic discharges
Source: Dr Khushnuma Mansukhani, Department of Electrophysiology, Bombay Hospital Institute of Medical Sciences, Mumbai.

in younger children and hence are important to pediatricians. As consanguinity is a custom in some communities in India and hence autosomal recessive LGMDs are seen frequently.

Many forms of LGMD have been documented **(Table 4)** in literature. Amongst these, α- and γ-sarcoglycanopathies and α-dystroglycanopathies are more likely to present in 1st decade of life. When they do so, the clinical presentation is similar to DMD, with large calves, proximal weakness, Gower sign and toe walk. As these are autosomal, girls can be severely affected as well. When female members are not affected in sarcoglycanopathies, the differentiation from DMD becomes difficult. Patient with DMD are more likely to have significant heart involvement and mental sub-normality than LGMD. LGMD 2K, 2M, 2N and 2O are called the α-dystroglycanopathies. At times, children can present as congenital muscular dystrophy, very early in life.

In LGMDs, selective involvement muscle groups leads to unique appearance in muscles **(Box 4)**. Symptomatic cardiac involvement is more common in autosomal dominant LGMDs than autosomal recessive. Conduction defects and cardiomyopathies are known. The autosomal recessive types of LGMD are associated with a much higher level of CK elevation than the dominant forms of LGMD, with exception of LGMD1C. Further, within the recessive forms, LGMD2B, 2I and sarcoglycanopathies are usually associated with very high CK levels.

BOX 4 Selective involvement of muscle groups

- *Lumps and bumps* of quadriceps in LGMDs
- *Biceps lump* in dysferlinopathy **(Fig. 13)**
- *Diamond sign* (prominence of anterolateral aspects of thigh on partial contraction of quadriceps) in dysferlinopathy
- *Calf head on trophy sign* in miyoshi myopathy.

Presence of inflammatory cells in various types of LGMDs, especially in dysferlinopathy, often leads to an erroneous diagnosis of inflammatory myopathy. However, unlike polymyositis, the inflammatory cells usually do not invade non-necrotic muscle fibers. Hence, evaluation of all changes in the biopsy is important. In calpainopathies, the inflammatory cell infiltrate may contain eosinophils, leading to confusion with eosinophilia myositis. Muscle biopsy immunoanalysis can suggest the diagnosis in almost 70% LGMDs. Western blotting of these proteins is more reliable in deciding primary and secondary deficits. Mutation testing is now the gold standard for diagnosis. A firm diagnosis provides management guidance, including the need for cardiac and respiratory surveillance which is particularly important in LGMD 1B, 2C-F and 2I.

Facioscapulohumeral Dystrophy

This is a slowly progressive autosomal dominant muscular dystrophy. Two variant are known. The typical or facioscapulo-humeral dystrophy (FSHD) 1, results from deletion in a 3.3 kb repeating sequence termed as D4Z4 at chromosome 4q35. Approximately 5% patients with FSHD have hypomethylation of this sequence, termed FSHD 2. The responsible gene is DUX4. Over expression of DUX4 is a result of hypomethylation and dysregulation of transcription of other genes. In FSHD1 larger size of the deletion leads to a more severe disease.

Clinical features Facioscapulohumeral dystrophy usually presents in adolescence. Patients have shoulder girdle and bifacial weakness **(Figs 13 and 14)**. The fixators of scapula are particularly weakened and lead to chicken wing appearance. Over-riding of scapula restricts abduction of shoulder and gives false impression of deltoid weakness. The deltoid muscles are in fact strong till late in the illness. Usually biceps waste less than the triceps, and the brachioradialis muscles even less, gives Popeye effect (thin upper arm and relatively preserved forearm). Wrist flexors are usually stronger than the extensors. Unlike most muscular dystrophies, FSHD tends to be asymmetrical, at times remarkably so. In the lower limbs, hip flexors, quadriceps, ankle dorsiflexion followed by ankle plantar flexion is the usual order of involvement. Weakness of ankle dorsiflexion in face of stronger plantar flexion leads to

Abbreviations: AR, autosomal recessive; AD, autosomal dominant; CK, creatine kinase; EMG, electromyography; FKRP, Fukutin-related protein; POMT, Protein O-mannosyltransferase 1; POMGnT, O-mannose-β-1,2-N-acetylglucosaminyltransferase; GNE, glucosamine (UDP-N-acetyl)-2-epimerase/N-acetylmannosamine kinase; ACEI, angiotensin converting enzyme inhibitors.

equinovarus contracture of foot, making the use of an ankle foot orthoses impossible. The Beevor sign, an upward movement of the umbilicus on flexing the neck as a result of weakness of the lower abdominal muscles, is common. Severe infantile form is well known. Association with sensorineural hearing loss and exudative retinal detachment (Coats' disease) exists in minority of patients. Frequently examination of family members for subtle signs of facial weakness or scapular winging gives immediate diagnostic clue. Other known phenotypic variants are (a) the face sparing variant, (b) with external ophthalmoplegia and (c) limb-girdle pattern of weakness.

Management Serum CK level is elevated several folds above normal. EMG shows myopathic potentials. Muscle biopsy shows dystrophic changes with characteristic angular fibers. Dystrophic changes may be less prominent in some biopsies, and the main change may be the angulated fibers, raising doubts about a neurogenic pathogenesis. DNA studies reliably establish the diagnosis. In indicated cases, surgical stabilization of scapula is beneficial. Trials of prednisolone or β-agonist (albuterol) have been known to result in transient benefits in a proportion of sufferers.

Distal Muscular Dystrophies

As distal weakness is more often a feature of neurogenic disorders, these myopathies are often confused with hereditary or acquired neuropathies or motor neuron disease. Sparing of the extensor digitorum brevis muscle is an important distinctive feature. Elevated CK and EMG distinguish it from neuropathic disorder. Other myopathies with distal weakness like myotonic dystrophy type 1, inclusion body myositis and myofibrillar myopathy form the differential diagnosis. Age of onset, inheritance pattern, histopathology, and pattern of weakness are most useful in distinguishing the individual distal myopathies. Although the group of distal myopathies starts distally or in some cases semi-distally, as the disease progresses, it involves proximal muscles. Distal myopathies patient are helped by symptomatic treatments like cock-up splint or ankle-foot orthoses.

Table 5 highlights salient features of individual distal myopathies. Markesbery-Griggs, Udd, and Welander are other distal myopathies presented in adulthood.

IN A NUTSHELL

1. DMD is X-linked recessive, the most common muscular dystrophy of young age with positive Gower sign, pseudohypertrophy of muscles, significantly elevated CK and readily diagnosed with the help of genetic testing.
2. BMD is a milder form of DMD, having better prognosis.
3. Upper limb onset, early contracture and cardiac complication favors the diagnosis of EMD.
4. Delay development since birth, intellectual disability, contracture and imaging abnormality suggests congenital muscular dystrophy.
5. Myotonia, systemic manifestation, weakness, positive family history and characteristic electrophysiological abnormalities confirm the diagnosis of myotonic dystrophy.
6. Asymmetrical differential muscle weakness in facial and upper girdle region with scapular winging suggests FSHD.
7. Limb-girdle muscular dystrophies consist of a wide group of autosomal muscular dystrophies having predominant proximal muscle weakness, contributory family history, variable elevated CK and variable systemic involvement. Weaker hip adductor over hip abduction favors LGMD more than DMD.

Chapter 43.7
Congenital Muscular Dystrophy
Sunil Pradhan, AK Meena

Congenital muscular dystrophy (CMD) is genetically heterogeneous group of disorders in which the affected infants typically appear *floppy* with low muscle tone, poor spontaneous movements, joint contractures and spinal rigidity. Muscle weakness which is predominantly proximal, typically presents at birth or early infancy and is very slowly progressive with periods of nearly stationary course in between. Joint contractures and spinal deformities contribute to the disability and respiratory compromise. Since delay of motor skill acquisition may be a presenting symptom of CMD, onset of manifestations before the age of two years is generally taken as important criteria for its diagnosis. The muscle weakness of CMD may be stable in the short-term, but typically over time the weakness and its related complications worsen. Apart from muscle, connective tissue and brain, heart and eye are the other organs which are often involved in this disorder.

The condition was first described by Batten in 1903 and subsequently the term congenital muscular dystrophy was coined by Howard in 1908. Other varieties of CMD were described by Ullrich in 1930 and Fukuyama in 1960. Later on, a Finnish variant called muscle-eye-brain disease or Walker-Warburg syndrome was described.

PREVALENCE

Fukuyama congenital muscular dystrophy is fairly common in Japan. It is approximately half as common as Duchenne muscular dystrophy (DMD). The estimated prevalence is approximately 7–12 cases per 100,000 children. The prevalence of all congenital muscular dystrophies has been estimated to be 4.7 cases per 100,000 children in Italy, while in Sweden the incidence is estimated at 6.3 cases per 100,000 births. Genetic mutations are identifiable in only about 25–50% of patients with CMD.

SUBTYPES

The CMD subtypes are mainly grouped on the basis of gene mutations and the abnormalities in the gene product **(Table 1)**. The common subtypes are: (1) laminin-α2 (merosin) deficiency (MDC1A), (2) collagen VI-deficient CMD, (3) *SEPN1*-related CMD (previously known as rigid spine syndrome, RSMD1), (4) dystroglycanopathies (caused by mutations in *POMT1, POMT2, FKTN, FKRP, LARGE, POMGNT1,* and *ISPD*) **(Box 1)**, and (5) *LMNA*-related CMD (L-CMD). Several less known CMD subtypes have been reported in a limited number of individuals.

Cognitive impairment ranging from intellectual disability to mild cognitive delay, structural brain and/or eye abnormalities, and seizures are found almost exclusively in the dystroglycanopathies while white matter abnormalities without major cognitive involvement tend to be seen in the laminin-α2-deficient subtype. Besides clinical similarities these genetically different disorders also have histopathological similarities. Muscle biopsy would

Abbreviations: MDC1A, merosin-deficient congenital muscular dystrophy type 1A; MDC1C, merosin-deficient congenital muscular dystrophy type 1C (with muscle hypertrophy); MDC1D, merosin-deficient congenital muscular dystrophy type 1D (with intellectual disability and abnormal glycosylation); WWS, Walker-Warburg syndrome; FCMD, Fukuyama CMD; MEB, muscle-eye-brain (disease); CMD, congenital muscular dystrophy; LGMD2I, limb-girdle muscular dystrophy type 2I (no intellectual disability); LGMD2K, limb-girdle muscular dystrophy type 2K with microcephaly, intellectual disability, normal MRI; LGMD2M, limb-girdle muscular dystrophy type 2M (no intellectual disability); LGMD2N, congenital muscular dystrophy/limb-girdle muscular dystrophy type 2N (intellectual disability); EDMD, Emery-Dreifuss muscular dystrophy.

show dystrophic features such as small, round fibers with fiber-size variability, immature muscle fibers, and occasional necrotic muscle fibers along with a more characteristic finding of marked increase in endomysial and perimysial connective tissue. The inheritance of CMD is essentially autosomal recessive (AR) except some of the cases of collagen VI-deficient CMD and all the cases of LMNA-related CMD (L-CMD) which are inherited in an autosomal dominant manner (AD).

CLINICAL PRESENTATION OF SUBTYPES

CMD with Laminin-α2 Deficiency (MDC1A, Classic CMD, Merosin-Deficient CMD)

The most common CMD is laminin-α2 deficiency accounting for approximately 40% of all cases. It is characterized by decreased fetal movements. Infants may have gross hypotonia, feeding and breathing difficulties and weakness during the first few months of life. Contractures are common. Most children eventually attain sitting but standing and walking with support is acquired only in 25%. External ophthalmoplegia is rare and occurs late. Some may develop enlarged head. Weakness is static or minimally progressive, but children often die 10–30 years later due to respiratory failure. Cardiac abnormalities (in one-third of patients), respiratory failure, feeding difficulties and scoliosis are the associated complications. Some patients may have a sensory motor demyelinating neuropathy which may be insignificant. Seizures occur in 20–30% cases. Cognitive abilities are usually normal in spite of MRI findings that are visible after age 6 in the form of periventricular white-matter hypomyelination **(Figs 1A to D)**. Structural brain changes like enlargement of the lateral ventricles, focal cortical dysplasia, occipital polymicrogyria and/or agyria, and hypoplasia of the pons and/or cerebellum may be seen in some patients **(Figs 1A to D)**.

Apart from this classical presentation of laminin-α2 deficient CMD, three different clinical variants are known to exist. These are:
1. Some rare patients with partial laminin-α2 deficiency present with hypotonia during the first year, but they become ambulatory and maintain ambulation for many years.
2. Some may present with a limb-girdle phenotype or with a phenotype resembling rigid spine muscular dystrophy (RSMD) or Emery-Dreifuss muscular dystrophy. In such patients, MRI abnormalities, seizures, and demyelinating neuropathy are the clues to suspect laminin-α2 deficiency.
3. Patients with complete lack of merosin are more severely affected, often presenting within the first week of life, requiring ventilatory support and enteral feeding.

Collagen VI Deficient CMD

This subtype of CMD is due to mutation in the gene for collagen type VI. Although originally described as separate entities, Ullrich CMD and Bethlem myopathy represent a clinical continuum of Collagen VI deficient CMD; intermediate phenotypes are also common. Three phenotypes have been described in individuals with collagen VI myopathy: (1) early and severe (ambulation never achieved), (2) moderate progressive (ambulation attained and lost), (3) mild (ambulation into adulthood).

Ullrich Congenital Muscular Dystrophy

It is an autosomal recessive disorder due to mutation in the gene for collagen type VI. The characteristic features include hypotonia in the neonatal period, kyphosis of the spine, torticollis, facial dysmorphism (micrognathia, prominent ears drooping of lower eyelid and round facies) and hip dislocation. Proximal joint contractures and distal hyperlaxity are characteristic **(Figs 2A[a to h] and B[a to d])**. A protruding calcaneus may also be seen. Most patients never walk and the weakness involves more proximal than distal muscles. In children who walk, progressive disability, usually due to contractures, lead to loss of ambulation after 3–10 years. Lax joints may become contracted. Respiratory failure invariably develops in the first or second decade. Skin manifestations like follicular hyperkeratosis, keratosis pilaris, and keloids may be seen. Patients have normal intelligence and brain MRI.

Bethlem Myopathy

Bethlem myopathy is due to autosomal dominant mutations in the same gene for collagen type VI. It is the milder form of Ullrich CMD. Typical features of Bethlem myopathy include: Onset in the first or second decade, but it may be as late as sixth decade; Flexion contractures are seen in the fingers, wrists, elbows, and ankles. Contractures may improve in childhood. Patients have weakness involving proximal and respiratory muscles. Rarely patients have no weakness. Weakness is slowly progressive. Patients usually have a normal life expectancy. Mild improvement may occur around puberty. In adults, progression may result in need for a wheelchair after 40–50 years. In intermediate cases, features of both diseases are noted with childhood-onset weakness, Ullrich like distal laxity, and Bethlem like contractures of finger flexors. Severe cases are similar to Ullrich congenital muscular dystrophy. A limb girdle muscular dystrophy (LGMD*)* phenotype with no significant contractures has been described. Some cases present with contractures without weakness and a Woody feeling upon palpation of muscles (myosclerosis).

Congenital Muscular Dystrophy with Rigid Spine (RSMD1 or *SEPN1*-related CMD)

Clinical presentation is at birth or within the first year of life, with variable degrees of cervicoaxial weakness and hypotonia early in life. The clinical features are rather homogenous. Most patients eventually walk, but in rare and severe cases, patients never gain independent ambulation. Scapular winging and facial and bulbar weakness are common. In contrast to Ullrich congenital muscular dystrophy, contractures are not present at birth, but they usually develop at age 3–10 years. The most characteristic pattern is spinal rigidity and scoliosis. Contractures of the face, proximal limbs, and finger extensors may also be present. Body mass index may be low in some patients. Respiratory insufficiency is common and progressive and may be more severe than limb weakness. Ventilatory assistance may be needed as early as the first decade of life to treat nocturnal hypoventilation a distinct feature of this type of CMD. Ambulation may be maintained for many years. Heart is usually normal but conduction blocks have been reported. Mental retardation is not a feature and imaging of brain is normal. The condition results from mutation in the *SEPN1* gene
Figures 1A to D CMD with laminin-α2 deficiency. (A and B) Showing contractures in the patient; (C) MRI of brain showing hypointensity on T1 images and hyperintensity of white matter in T2 images suggesting hypomyelination; (D) Histology of merosin deficient congenital muscular dystrophy

that encodes for a protein found in endoplasmic reticulum called selenoprotein N.

There is another gene defect that results in a phenotype similar to axial muscular dystrophy similar to SEPN-1 related myopathies; in patients with a mutation in selenocysteine insertion sequence-binding protein 2 (SECISBP2, SBP2), there is a multisystem disorder that includes axial muscular dystrophy and other features such as azospermia, cutaneous photosensitivity, impaired T-cell proliferation, increased fat mass with enhanced insulin sensitivity, and hearing loss. MRI shows selective involvement of the sartorius

and major adductor muscles in the thigh. This gives a characteristic medial thigh wasting, notable on physical examination.

RSMD1 is caused by *SEPN1* mutations and has normal expression of the protein merosin. However it is now known that *rigid spine syndrome* is not specific to this subtype and that some spinal rigidity resulting from paraspinal contractures may develop in other CMD subtypes. *SEPN1* mutations are also reported in the classic form of multiminicore myopathy, in congenital fiber-type disproportion myopathy, and in a desminopathy with Mallory body-like inclusions.

Figures 2A (a to h) Ullrich congenital muscular dystrophy (UCMD). (a) Severe contracture of the shoulder, elbow joints, hips and knee joints, slender habitus with generalized muscle wasting and particularly of distal upper limb. (b) Hyperextensibility of the interphalangeal joints. (c) Hyperlaxity of the ankle joint. (d) Hyperextensibility of the wrist. (e) Classical protuberant calcanei. (f to h) Typical velvety palms and soles and almost total absence of the major palmar and plantar creases

Alpha-dystroglycanopathy (Glycosyltransferase Deficiency)

Initially, mutations in different genes were thought to cause separate disorders. Presently mutations in 12 genes involved in glycosylation of α-dystroglycan are known to cause congenital muscular dystrophy. It is now known that mutations in these genes result in overlapping phenotypes with a wide range of phenotypic heterogeneity. Similarly, a single phenotype can be caused by more than one gene mutation. In these CMDs, the severity of changes in affected tissue has an order of rank based on the degree of preserved α-dystroglycan function. In the mildest disease, only the skeletal muscle is affected. This is classified by online mendelian inheritance in man (OMIM) as type C; limb-girdle phenotype. Type B represents moderate dystrophic changes in the muscle resulting in congenital onset with or without mental retardation. As severity progresses, the cerebellum and then the pons, eyes, and cerebrum are affected. This most severe form is classified by OMIM as type A; congenital with brain and eye abnormalities. Again the eye and pontocerebral involvement may have mild to severe degree.

Each affected tissue shows an order of worsening severity. In mild disease, patients may have normal muscle and only mild eye and cerebellar abnormalities. In intermediate disease, patients may have mild dystrophic changes, myopia, pontocerebellar hypoplasia, and focal pachygyria. In severe disease, patients may have active muscle fiber degeneration and necrosis, nonfunctioning eyes, severe pontocerebellar hypoplasia, and agyria. In general brain, MRI may show structural abnormalities like hydrocephalus, brain stem hypoplasia, cerebellar cysts; or abnormalities in neuronal migration (cobblestone lissencephaly or polymicrogyria) **(Figs 3A to F)**. With time white matter changes may regress. Various forms [most severe forms are Fukuyama congenital muscular dystrophy (FCMD), Muscle-eye-brain (MEB) disease, Walker-Warburg syndrome (WWS)] of alpha-dystroglycanopathies are described below:

Fukuyama Congenital Muscular Dystrophy (Mutation in Fukutin)

Patients often present in utero with decreased fetal movements poor sucking, lack of head control, and a weak mouth in neonatal period. At age 2–8 years, most patients stand or walk few steps, but patients with severe disease may be able to sit only with
Figure 2B (a to d) Histology of UCMD: Transversely cut skeletal muscle tissue showing (a) normal polygonal fibers (HE) (b) Normal preserved expression of *Col6A1* in all fibers (c) rounding and variation in fiber diameter (HE) (d) loss of expression of *Col6A1* in all the fibers

support. Progressive weakness and respiratory failure follows, with death usually occurring in the mid teens. However, death can occur as late as the mid 20s or as early as age 2 years. Cardiac disease develops after the age of 10 years, resulting in dilated cardiomyopathy and congestive heart failure in most patients. Eye movement abnormalities, poor pursuits, and strabismus are seen in milder cases and retinal detachment, microphthalmos, cataracts, hyperopia, or severe myopia are seen in severe forms. Cerebral changes are always present which include Type II lissencephaly or cobblestone lissencephaly (a finding which is considered a classic finding in this disease as well as in all other glycosyl-transferase deficiencies), cobblestone polymicrogyria **(Figs 4A to C)** and/or pachygyria to complete agyria due to neuronal migration abnormalities, dysplasia of the pyramidal tracts, ventricular dilation and delayed myelination. Cerebellar cysts are common **(Fig. 4)**. Seizures occur in about 50% of patients. Mental retardation is usually present. Two families with three affected children with a limb girdle phenotype (LGMD2M) and a mutation in *fukutin was* reported. Onset was before 1 year with hypotonia. Deterioration occurred with febrile illness and there was improvement with corticosteroids. Intelligence and brain MRI were normal. Dilated cardiomyopathy with no or minimal limb girdle muscle involvement and normal intelligence can be the sole manifestation in 2nd to 5th decades.

Muscle-Eye-Brain (MEB) Disease

Mutations in *POMT1*, *POMT2*, *POMGnT1*, *FKRP,* and *LARGE* can cause this syndrome. The incidence varies in different studies. Severity of the phenotypes also varies. Severely affected patients cannot sit or turn, they lack visual contact, and they often die in the first 1–2 years. Moderately affected patients can often sit and speak a few words. They may have severe myopia, but they can make visual contact. Mildly affected patients may be able to walk for a short time, they can speak in sentences, and they have preserved vision. Seizures are common and severe but similar to those of Fukuyama congenital muscular dystrophy. CNS abnormalities are always present, including moderate-to-severe mental retardation. Cerebral changes are similar but variable to those of Fukuyama congenital muscular dystrophy.

Walker-Warburg Syndrome

It is the most severe form of congenital muscular dystrophy and is caused by mutations in all glycotransferases. They manifest in utero or at birth, with hypotonia, poor sucking, swallowing and contractures. It is progressive and the average time to death is 9 months. Associated eye abnormalities include microphthalmos, hypoplastic optic nerve, ocular colobomas, retinal detachment, cataracts, glaucoma, iris malformation, and corneal opacities, all leading to blindness. Complete type II lissencephaly with agyria, thin cortical mantle, an absent corpus callosum, fusion of the
Figures 3A to F Alpha-dystroglycanopathy. (A and B) A 4-month-old male child with macrocephaly, development delay, seizures, hypotonia, brisk reflexes, ankle contractures, hypogonadism, EOM abnormality and high CK levels. MRI brain showing Type 2 (cobblestone) lissencephaly in the child diagnosed as Alpha dystroglycanopathy. [T1-weighted axial view and coronal view] The cortex shows a bumpy surface and is less markedly thickened than in type I lissencephaly. The underlying white matter is abnormally hyperintense due to abnormal myelination. In the posterior fossa cerebellar cortical dysgenesis is revealed by the bumpy surface of both hemispheres and multiple subcortical cysts (arrow). (C) Chorioretinitis with disc pallor. (D-F) Histology pictures
Figures 4A to C Fukuyama congenital muscular dystrophy. (A) Axial T1 and (B) T2-weighted images shows thickened, polymicrogyric cortex in the frontal lobes and perisylvian regions, with preserved cortical architecture in the temporal and occipital lobes. There are patchy foci of delayed myelination in the cerebral white matter. Coronal T2-weighted image (C) shows disorganized cerebellar cortex with small subcortical cysts

cerebral hemispheres and hypoplasia of the pyramidal tracts are the brain abnormalities seen in these patients. Severe cerebellar atrophy of the vermis and hemispheres, arachnoid cysts, and a hypoplastic brainstem are also the features in the posterior fossa. Meningocele or encephalocele is seen in 25% of patients. Common are microcephaly, ventricular dilation, and obstructive hydrocephalus **(Figs 5A to C)**.

CMD with mental retardation but no or mild structural brain abnormalities forms the intermediate form. In the mildest cases, presentation is with a LGMD phenotype (LGMD2K or LGMD 2N). Presentation is within the first decade with proximal weakness. The course is slowly progressive. Mild-to-moderate mental retardation is present, while only mild or no structural brain abnormalities have been described. It appears that most if not all patients with *POMT1* mutations have either structural or functional brain disease. This is not true for the mildest cases with mutations in *fukutin*, *FKRP*, and *POMGnT1* in which mild cases may have no structural or functional brain defects. α-dystroglycan staining, mutations in *POMT1* were the most frequent (25–40%) cause of alpha dystroglycanopathy.

Some specific gene defects that lead to abnormal glycosylation of alpha-dystroglycans and have variable clinical presentation have been described:

FKRP (Fukutin Related Protein)
Congenital Muscular Dystrophy

Spectrum of disease phenotypes is varied ranging from in-utero or lethal Walker-Warburg syndrome or muscle-eye-brain disease to intermediate forms (CMD with cerebellar involvement and CMD with mental retardation and microcephaly) to a mild limb-girdle muscular dystrophy phenotype. Associated brain manifestations are pontocerebellar hypoplasia, cerebellar cysts, agyria, thick frontal cortex, myopia, and retinal detachment. Dystrophy with mild mental retardation and cerebellar cysts has been described. An intermediate form is similar to congenital muscular dystrophy due to laminin-α2 mutations. In addition to hypotonia and weakness at birth and delayed motor milestones, hypertrophy of the legs and tongue is noted. Atrophy of proximal muscles and facial weakness are usually present with dilated cardiomyopathy and normal intelligence and brain imaging.

Milder cases present with a limb-girdle phenotype and are allelic with limb-girdle muscular dystrophy type 2I. Age at presentation varies from first year to the teens to mid adulthood. Scoliosis and ankle contractures similar to those of Duchenne muscular dystrophy with loss of ambulation occurring in the teens can also be seen. Muscle and tongue hypertrophy is common. Facial weakness is often present. Respiratory failure in the second decade often leads to death or the need for ventilatory assistance. With onset in the teens or adulthood, ambulation can be preserved until the sixth or seventh decade, but respiratory failure may develop before the sixth or seventh decade. Dilated cardiomyopathy develops in 50% of patients.

POMT1 and POMT2 Congenital Muscular Dystrophy

A wide spectrum of disease manifestation has been described, ranging from severe cases presenting as Walker-Warburg syndrome and mild cases presenting as a LGMD classified as LGMD2K (*POMT1*) and LGMD2N (*POMT2*). Severe cases have structural brain defects similar to those in Walker-Warburg syndrome or muscle-eye-brain disease.

CMD with mental retardation but no or mild structural brain abnormalities forms the intermediate form. Mildest cases present with LGMD phenotype (LGMD2K or LGMD 2N). They present within the first decade with proximal weakness. The course is slowly progressive. Mild-to-moderate MR is present. Most if not all patients with *POMT1* mutations have either structural or functional brain disease. This is not true for the mildest cases with mutations in *fukutin*, *FKRP*, and *POMGnT1* in which mild cases may have no structural or functional brain defects. Mutations in *POMT1* and POMT2 were the most frequent (25–40%) cause of alpha dystroglycanopathy.

LARGE Congenital Muscular Dystrophy

Mutations in the *LARGE* gene are the rarest cause of CMD with defect of α-dystroglycan glycosylation. Five cases were reported from 3 families. One case has been described in a 17-year-old female adolescent who presented with weakness and hypotonia at age 5 months. She had profound mental retardation and an MRI that showed mild white-matter abnormalities and structural malformations suggestive of aberrant neuronal migration.
Figures 5A to C Walker-Warburg syndrome Axial T1 weighted (A) and coronal T2 weighted (B) images show gross hydrocephalus. The cortex shows absence of gyri and is lissencephalic. Sagittal T2 weighted image (C) shows hypoplasia and superior rotation of the cerebellar vermis. The brainstem is dysmorphic and shows a characteristic 's' shape. Also note the hypertrophic tectum and occipital encephalocele that are common association with this condition

An abnormal electroretinogram suggested eye abnormalities. Presentation was in the first year of life with hypotonia and delayed motor and cognitive milestones. They walked at 2 years, but with difficulty and muscle hypertrophy was noted. Mental retardation was present. Only mild eye abnormalities were noted, but severe abnormalities on brain MRI were seen including ventricular dilatation, cerebellar hypoplasia, high signal periventricular and deep white matter abnormalities, and in the more affected sibling pachygyria of the frontal lobes. Two siblings with consanguineous parents had a phenotype similar to Walker-Warburg syndrome and they died within 6 months CKs were markedly elevated. Both had eye abnormalities and brain imaging showing severe hydrocephalus and structural brain disease.

LMNA-deficient CMD (L-CMD)
The phenotype is caused by a mutation in the gene that encodes for proteins laminin A/C, also called LMNA. A wide variety of phenotypes including a CMD with rigid spine, Emery-Dreifuss muscular dystrophy, familial partial lipodystrophy, limb girdle muscular dystrophy, dilated cardiomyopathy, is caused by mutations in LMNA gene. Rarely neuropathies and dermal changes may also occur. LMNA-related CMD (L-CMD) also called as nuclear envelopathies, is part of the spectrum of laminopathies. L-CMD may present in the first six months of life as dropped head syndrome (absence of head or trunk support) or with progressive loss of head support after acquisition of sitting or walking ability. Hypotonia and weakness involves the axial-cervical muscles followed by more slowly progressive weakness of proximal upper limbs and distal lower limbs. Facial muscles are spared. With time, there is head lag, thoracic and lumbar spinal hyperextension (rigidity), lower limb contractures with no significant upper limb contractures and talipes equinovarus. Mechanical ventilation may be required before age two years in those more severely affected. L-CMD can be considered as an early-onset variant of Emery Dreifuss muscular dystrophy (EDMD) but they lack some of the typical early findings of EDMD, i.e., elbow contractures and major cardiac complications. They may develop in time. Genetic testing has identified a number of de novo dominant mutations.

Rare CMDs
A few rare disorders have been described with wide variety of clinical features related to different systems of the body along with musculoskeletal features of CMD. Some of these are as follows:

Integrin-alpha7 Deficiency
This rare disorder has been described in only a few children, who presented with hypotonia in infancy and delayed motor milestones (e.g., walked at age 2–3 years) mental retardation, contractures and respiratory failure.

CMD with Familial Junctional Epidermolysis Bullosa
Epidermolysis bullosa and muscular dystrophy first described in 1970s was subsequently described in several reports. The skin lesion include nail dystrophy, scalp alopecia and bullous lesions, which can be severe, even resulting in death and patients present with severe blistering often secondary to trauma or heat. Proximal muscle weakness is progressive often leading to wheelchair use by the second decade and may correlate with residual plectin function. Myasthenic syndrome has also been described with ptosis, ophthalmoplegia and facial weakness and may respond to pyridostigmine. Growth retardation, anemia, laryngeal webs, tooth decay, pyloric atresia, infantile respiratory insufficiency, and cardiomyopathy are the other systemic features. Presentation may then be as a late onset (20–40 years) muscular dystrophy. An LGMD syndrome without epidermolysis bullosa has been described as

presenting in early childhood with delayed walking. Proximal weakness eventually progresses and results in loss of ambulation.

CMD with Mitochondrial Structural Abnormalities
The defect in this phenotype is a mutation in the choline beta kinase gene. It is characterized by marked mental retardation microcephaly apart from hypotonia starting in early infancy and generalized muscle weakness. Some patients may have dilated cardiomyopathy and ichthyosiform skin changes.

DIFFERENTIAL DIAGNOSIS
Congenital muscular dystrophies need to be distinguished from other muscle diseases, anterior horn cell disease and central nervous system diseases with muscle weakness and low muscle tone:

Congenital Myopathies
X-linked myotubular myopathy, central core disease, centronuclear myopathy, and nemaline myopathy should be differentiated from CMD. Severity of presentation can range from decreased fetal movements or congenital floppy infant syndrome requiring mechanical ventilation to later-onset milder symptoms. Significant joint contracture is not a feature. Severe facial weakness or ophthalmoparesis seen in certain congenital myopathies is not found in the early stages of CMD, but may occur in the late stages of the subtype's laminin-α2 deficiency and the dystroglycanopathies. Congenital myopathy caused by RYR1 mutation can mimic SEPN1-related CMD with a clinical picture of multiminicore myopathy or a CMD-like presentation, with early onset hypotonia, axial weakness, and respiratory insufficiency. They typically have normal or near-normal serum CK concentration and histopathological evidence of developmental/structural muscle changes rather than dystrophic changes on muscle biopsy.

Limb-girdle Muscular Dystrophy
It is strictly the age of onset of muscle weakness in late childhood or adulthood that defines LGMD. The disease spectrum within the dystroglycanopathies ranges from congenital onset with or without CNS and eye involvement, to mild development delay, to a later-onset muscle weakness or limb-girdle muscular dystrophy with or without intellectual disability. Mutations in any of the six dystroglycanopathy-associated genes can result in CMD or LGMD. Similarly, the milder collagen VI-deficient myopathies can mimic LGMD.

Myotonic Dystrophy Type 1 (DM1)
This is an autosomal dominant multisystem disorder that affects skeletal muscle and smooth muscle as well as the eye, heart, endocrine system, and central nervous system; clinical severity of the phenotype ranges from mild to severe. Congenital DM1 is the severe early-onset form, characterized by hypotonia and severe generalized weakness at birth, often with respiratory insufficiency and early death; intellectual disability is common. Diagnosis is based on detection of an expansion of the GTC trinucleotide repeat in DMPK gene.

Pompe Disease (Glycogen Storage Disease Type II, GSD2, Acid Maltase Deficiency)
Hypotonia within the first few months of life, head lag, and marked cardiomegaly can also be a presenting manifestation of Pompe disease. Respiratory insufficiency in the first year can lead to frequent pulmonary infections. Other associated features include moderate hepatomegaly and macroglossia. Diagnosis is confirmed through identification of mutation in GAA, the gene encoding alpha-glucosidase (GAA), or by measuring deficient serum GAA

enzyme (also called acid maltase) activity. A later-onset phenotype may include nonprogressive or slowly progressive proximal muscle weakness, spinal stiffness without major limb contractures. Progressive respiratory failure results from diaphragmatic failure. This clinical picture may overlap with other congenital muscular dystrophies associated with rigid spine syndrome and particularly *SEPN1*-related CMD.

Congenital Onset of Facioscapulohumoral Muscular Dystrophy (FSHD)

It is characterized by congenital facial weakness, congenital deafness, mental retardation, and seizures. Facial weakness is the earliest and most prominent sign, distinguishing FSHD from CMD: Most children become wheelchair bound in childhood. Infantile FSHD may be inherited as a *de novo* mutation or in autosomal dominant fashion. FSHD is diagnosed by a molecular genetic test that identifies deletion of integral copies of a 3.3-kb DNA repeat motif, D4Z4, which is located in the subtelomeric region of chromosome 4q35.

Mitochondrial Myopathies

These have overlapping features including CNS involvement and are often associated with oculofacial involvement. Variability in weakness and fatigability is an important clinical clue. Overall, the diagnosis is based on specific morphological findings on biopsy, biochemical changes, and molecular genetic testing.

Spinal Muscular Atrophy (SMA)

It is an autosomal recessive disease characterized by progressive muscle weakness and atrophy. The onset of weakness ranges from before birth to adolescence or young adulthood. Diagnosis is based on electromyography showing neurogenic changes, histological findings of denervation atrophy on muscle biopsy and molecular genetic testing of *SMN1* and *SMN2 genes*, the two genes known to be associated with SMA.

Congenital Myasthenic Syndromes (CMS)

These are a group of neuromuscular junction disorders leading to weakness and fatigability and often respiratory and feeding complications. Arthrogryposis; club feet resulting from fetal immobility; bulbar, oculomotor, or facial involvement; diurnal variability of performance; and unexpected rapid failure in motor, respiratory, and/or feeding functions are typical clinical findings but are not always present. Electrophysiologic studies including EMG with repetitive nerve stimulation and stimulated single fiber EMG may identify abnormal neuromuscular transmission but are often difficult and require expertise.

Rigid Spine

The phenotype, early-onset muscle disease associated with rigid spine is caused by many disease states. The differential diagnosis are CMD type laminin-α2 deficiency (MDC1A), Bethlem myopathy, early onset CMD with cerebellar hypoplasia, congenital myopathies (centronuclear myopathy caused by mutations in *DNM2*, the gene which encodes dynamin 2, central core disease and multiminicore disease, caused by mutations in *RYR1*, the gene encoding skeletal muscle ryanodine receptor) and glycogen storage disease type II (i.e., Pompe disease).

Prader-Willi Syndrome (PWS)

It is characterized by severe hypotonia and feeding difficulties in early infancy, followed in later infancy by excessive eating and gradual development of morbid obesity unless externally controlled. Individuals with PWS have a distinctive behavioral phenotype. Hypogonadism is present in both males and females. The methylation-specific pattern of the PWS/AS region of chromosome 15q11 establishes the diagnosis in more than 99% of individuals.

Marinesco-Sjögren Syndrome (MSS)

It presents with cerebellar ataxia, early-onset cataracts, and mild to severe mental retardation, hypotonia, and muscle weakness. Serum CK is two to four times normal. Diagnosis is confirmed by clinical picture, brain MRI cerebellar atrophy, electron microscopic changes (autophagic vacuoles, membranous whorls, and electron-dense double membrane structures associated with nuclei) on muscle biopsy, and molecular genetic testing of *SIL1*, the only gene known to be associated with MSS. It is inheritance as an autosomal recessive disorder.

DIAGNOSIS OF CMD SUBTYPES

Diagnosis of subtypes of CMD usually involves medical history, family history, physical examination, neurologic examination, eye examination by a pediatric ophthalmologist, serum CK concentration, neuroimaging, muscle imaging, muscle and/or skin biopsy for histologic examination and immunohistochemistry, and molecular genetic testing **(Flow chart 1)**.

Clinical Evaluation

Medical History

In infants, medical history focusing on fetal movement, perinatal history, acquisition of milestones, feeding ability and respiratory complications, such as aspiration because of poor cry and poor cough should be carried out. In older children, history of cognitive abilities, motor abilities, muscle weakness, disease progression, joint contractures, scoliosis and spinal deformities, nutritional status, signs of respiratory compromise, hospitalizations, and infections should be elicited. There are some clues that may help identify the specific CMD subtype:

1. Congenital head lag as a result of marked cervicoaxial hypotonia associated with progressive cervical stiffness: *SEPN1*-related CMD
2. CNS involvement, psychomotor delay or intellectual disability: dystroglycanopathies; occasionally, laminin-α2 deficiency
3. Early signs of respiratory insufficiency:
   a. Very severe or progressive in the first two years of life: L-CMD; some very hypotonic infants with laminin-α2 deficiency
   b. Slowly progressive resulting in severe respiratory insufficiency in the first decade:
      i. *Nonambulatory*: Laminin-α2 deficiency; collagen VI-deficient CMD; L-CMD; dystroglycanopathy
      ii. *Ambulatory*: *SEPN1*-related CMD
4. Orthopedic complications:
   a. *Diffuse proximal and distal contractures and spinal stiffness and/or scoliosis*: Collagen VI-deficient CMD and laminin-α2 deficiency; late-stage L-CMD and dystroglycanopathies
   b. *Selective involvement of the spine*: *SEPN1*-related CMD; early in the course of laminin-α2 deficiency in children who are ambulatory; collagen VI-deficient CMD; L-CMD
5. *Joint deformities, torticollis or hip dislocation at birth*: Collagen VI-deficient CMD
6. *Rapidly progressive course with loss of head control*: L-CMD (dropped head syndrome)

Family History

Most of the CMD are inherited in an AR pattern. In the non-consanguineous, small nuclear families, often only one individual in a family with an AR disorder is affected. In contrast, most individuals with collagen VI-deficient CMD and all reported individuals with L-CMD have a de novo autosomal dominant mutation and therefore represent a single occurrence in a family.

```

Floppy infant with normal strength:
• Hyper-reflexia
• Bilateral extensor plantars
• Global developmental delay
• Micro/macrocephaly
• Seizures

Cerebral causes:
• Hypoxic brain injury
• 21 trisomy
• Prader Willi syndrome
• Cerebral malformations
• **Zellweger** disease
• **Marinesco**-**Sjögren** syndrome

• Genetic analysis, karyotyping, VLCFA
• CT/MRI brain

Floppy infant with weakness (Lower motor neurone):
• Hypo/areflexia
• Delayed selective motor milestones
• Normal head size
• Severe proximal limb weakness
• Tongue fasciculations
• Feeble cry
• Myotonia (Congenital myotonic dystrophy)
• Paradoxical chest wall movement
• Ptosis, ophthalmoplegia, facial/bulbar paresis (CMS, congenital myopathy, mitochondrial)

• Joint contractures with distal hyperlaxity—collagen VI-deficient CMD
• Joint contractures without distal hyperlaxity—laminin alpha-2 deficiency
• Spinal stiffness without joint contractures—*SEPN1*-related CMD

CPK, RNS, NCS-EMG, MRI brain

• RNS (abnormal): congenital myasthenic syndromes
• NCS (abnormal) + EMG (normal): congenital hypomyelinating neuropathy
• NCS (normal) + EMG (abnormal):
    • Neurogenic-SMA
    • Myopathic-CMD, congenital myotonic dystrophy, congenital myopathies

Abnormal MRI brain—CMD
• Abnormal white matter changes not regressing with time—laminin alpha-2 deficiency

• Structural changes (including cobblestone appearance hydrocephalus, brainstem hypoplasia cerebellar cysts) or abnormalities in neuronal migration (lissencephaly or polymicrogyria) and white matter changes
• May regress with time—dystroglycanopathies

Appropriate genetic analysis based on above findings

If genetic analysis is inconclusive, then go for muscle biopsy with IHC

Physical Examination

Clinical clues include the following:

1. *Muscle pseudohypertrophy (calf and tongue)*: Dystroglycano-pathies (may resemble DMD).
2. *Diffuse joint contractures*: Laminin-α2 deficiency, collagen VI-deficient CMD.
3. *Distal hyperlaxity*: Collagen VI-deficient CMD.
4. *Hypertrophic scars or keloid formation*: Collagen VI-deficient CMD.
5. *Spinal stiffness without limb joint contractures: SEPN1-*related CMD.
6. *Axial hypotonia and weakness (poor trunk control) preceding spinal stiffness*: In early laminin-α2 deficiency, L-CMD, and collagen VI-deficient CMD.
7. *Cardiac involvement*: Rhythm disturbances in L-CMD; cardiomyopathy in dystroglycanopathies; right heart failure in any CMD subtype if chronic severe respiratory failure is untreated.
8. Nocturnal hypoventilation or respiratory failure in a person who is ambulatory: *SEPN1*-related CMD; occasionally collagen VI-deficient CMD.
9. The type and location of spinal deformity:
   a. Thoracic kyphosis: collagen VI-deficient CMD
   b. Thoracic lordosis: laminin-α2 deficiency, *SEPN1*-related CMD, and L-CMD; late stage of dystroglycanopathies. Lumbar hyperlordosis is frequently seen in all subtypes.
10. *Neurologic examination:* Features that may help in subtyping of specific CMD include:
    i. Head circumference: May be abnormal in laminin alpha 2 deficiency (macrocephaly) or in dystroglycanopathies (microcephaly or macrocephaly). Certain clinical findings can help direct one to the specific gene involved: microcephaly (*POMT1* and *POMT2);* macrocephaly and epilepsy (*POMGNT1);* cardiac involvement (*FKRP, FKTN, POMT1*)
    ii. CNS findings and abnormal white matter changes may be evident as:
        a. Pyramidal signs (hyper-reflexia, clonus) and cognitive involvement: dystroglycanopathies
        b. Seizures easy to control with routine antiepileptic drugs: typical for laminin-α2 deficiency
        c. Seizures refractory to polytherapy: often in MEB disease, especially those with *POMGNT1* mutations
        d. Intellectual disability associated with marked behavioral disturbances: suggestive of MEB disease, especially those with *POMGNT1* mutations.

Imaging

Neuroimaging MRI can guide diagnosis in CMD. The two CMD subtypes with abnormalities in brain imaging are laminin-α2 deficiency and the dystroglycanopathies.

1. In laminin-α2 deficiency abnormal white matter signal after age six months helps establish the diagnosis. White matter changes do not regress with time.
2. In the dystroglycanopathies, structural changes (including hydrocephalus, brainstem hypoplasia, cerebellar cysts) or abnormalities in neuronal migration (lissencephaly or polymicrogyria) are common. White matter changes may regress with time.

Muscle imaging Distinct recognizable patterns on muscle MRI in persons with spinal rigidity, normal merosin staining of skin or muscle biopsy, and normal serum CK levels can help differentiate between collagen VI-deficient CMD, *SEPN1*-related CMD, and L-CMD, and between the CMDs and the overlapping phenotypes considered in the differential diagnosis, caused by mutations in *RYR1*, *GAA* (encoding acid maltase) or *DNM2 genes.* Muscle MRI

can help differentiate muscular dystrophies with rigidity of the spine:

- *SEPN1:* There is selective involvement of the sartorius, and sparing of gastrocnemius
- *COL6A:* Bethlem myopathy patients had concentric atrophy and peripheral involvement, most clearly seen in vasti and gastrocnemius
- *COL6A:* Ullrich congenital muscular dystrophy (UCMD) patients had diffuse involvement of thigh muscles with selective sparing of anteromedial thigh muscles; more diffuse than Bethlem myopathy, but similar peripheral involvement of gastrocnemius
- *LMNA:* There is involvement of vasti at thigh level, medial > lateral gastrocnemius, and soleus muscle
- *LGMD2A (CAPN3):* Selective involvement of adductor magnus and posterior thigh muscles, medial > lateral gastrocnemius and soleus muscle.

Laboratory Evaluation

Serum CK levels In general CMD subtypes with positive merosin expression (collagen VI-deficient CMD, *SEPN1*-related CMD, L-CMD) show normal or mildly increased serum concentration of CK, while those with primary merosin deficiency (laminin-α2 deficiency) or secondary merosin deficiency (dystroglycanopathies) have high serum concentration of CK (> 4x normal values). In patients with congenital muscular dystrophy with familial junctional epidermolysis bullosa CK levels are usually more than 1000 IU/L.

Molecular genetic testing There is a trend recently to perform molecular genetic testing without muscle biopsy. This is due to the expanding role of molecular genetic testing in confirming the diagnosis of a CMD subtype. This is usually done, when the medical history, physical examination, and neurologic examination support the diagnosis of a CMD and a single gene defect is suspected as in laminin-α2 deficiency. In contrast, when multiple genes may need to be tested, as in the confirmation of the diagnosis of a dystroglycanopathy, performing immunohistochemical analysis of a muscle biopsy may identify the subtype prior to proceeding with molecular genetic testing. Two approaches can be followed: sequential molecular genetic testing or multigene testing. Once the disease-causing mutations are identified, molecular genetic testing of the parents is needed to clarify mode of inheritance and to provide accurate recurrence risk information to family members.

Muscle biopsy Histology typically shows a dystrophic or myopathic nonspecific pattern that does not suggest a congenital myopathy, mitochondrial disorder, or denervating disorder. The most significant dystrophic features are fiber size variability, presence of increased endomysial fibrosis, and variably necrotic and/or regenerative fibers **(Fig. 3)**. In some individuals with CMD, muscle biopsy may only show fiber size variation with absence of or only mild manifestations of fibrosis, necrosis, or regeneration. Inflammation may or may not be present. A muscle biopsy may be indicated if the diagnosis based on clinical examination remains unclear or molecular genetic testing does not confirm a diagnosis.

Immunohistochemical staining of muscle and/or skin can in some instances confirm protein deficiencies that can establish or exclude the diagnosis of a CMD subtype or confirm molecular genetic testing. Immunostaining of muscle can detect deficiencies of the proteins laminin-α2 (merosin), collagen VI, and alpha dystroglycan. Immunostaining of skin can detect deficiencies of laminin-α2 and collagen VI (**Fig. 3**). Immunostaining is not diagnostic or specific in *SEPN1*-related CMD or L-CMD. Partial merosin deficiency may be primary or secondary (i.e., caused by mutation in *LAMA2*, encoding laminin-α2 or caused by mutation of one of the genes associated with the dystroglycanopathy respectively. Plectin immunostaining is reduced in muscle Z-lines and skin in CMD with familial junctional epidermolysis bullosa.

TREATMENT

There is no definitive treatment for CMD. However, a multidisciplinary medical care improves quality of life and longevity in these patients. Management should be tailored to each individual, their CMD subtype, and rate of progression.

Assessment of respiratory function It is done with baseline lung function tests, including forced vital capacity in sitting and supine positions and blood gas analysis. Respiratory aids are provided to those with respiratory insufficiency and these include assisted cough and hyperinsufflation devices, Percussionaire, noninvasive ventilatory support, or mechanical ventilation via tracheostomy and chest physiotherapy.

Polysomnography This is to identify individuals with nocturnal hypoventilation and to evaluate individuals with symptoms of hypercapnea. This also helps in deciding about the requirement of ventilator support.

Assessment of muscle power Assessment of muscle power and joint contractures should be done by an occupational therapist and physical therapist.

Steroids In those who respond, the use of steroids appears to support prolonged ambulation. Assistance in education, and social and emotional support can improve the sense of social involvement and productivity and can reduce the sense of social isolation common in these patients.

Assessment of joint contractures and radiologic examination Assessment of joint contractures and spinal deformity should be done by orthopedic surgeon. Prevention of contractures and facilitate mobility by physical therapy and stretching exercises are helpful. Mechanical assistive devices including canes, walkers, orthotics, and wheelchairs can be used as needed to help ambulation and mobility. Posture in vertical, sitting, and supine positions is advised as improved posture may positively affect chest expansion.

Surgery Surgical intervention may be needed for orthopedic complications such as foot deformity, joint contractures, and scoliosis. Pros and cons of surgery for hip dislocation or joint contractures need to be considered in light of risk/benefit ratio.

Nutritional assessment and feeding Weight and height measurement, serum vitamin D and vitamin B12 levels, and calculation of body mass index should be done routinely. Most of the CMD patients have low body mass index and would require assisted feeding and nutritional supplements. Oral hygiene should also be taken care of.

Assessment of cardiac function It is required in all CMDs particularly those with dystroglycanopathy or L-CMD, with particular awareness that cardiomyopathy and/or arrhythmia can occur in the absence of severe muscle disease. Evaluation should also be done of secondary right heart failure and pulmonary hypertension in those with significant respiratory involvement.

Complete eye examination This should be done in all CMDs particularly in those with a dystroglycanopathy or if clinically indicated.

Speech therapy Several CMD patients require speech therapy due to involvement of brain and hypoventilation. Sometimes learning the use of gestures also helps in improving communication and quality of life.

PREVENTION

Prenatal testing and genetic counseling should be offered. Both molecular genetic testing and biochemical testing (for laminin-α2)

is possible if the disease-causing mutations in the family are known. Genetic status of the proband's parents decide the risk to the sibs of the proband. The risk to sibs is low, but greater than that of the general population if the disease-causing mutation found in the proband cannot be detected in the leukocyte DNA of either parent. This is because of the possibility of germline mosaicism. Carrier detection using molecular genetic techniques is possible if the disease-causing mutations in the family are known.

IN A NUTSHELL

1. CMD is a clinically and genetically heterogeneous group of inherited muscle disorders.
2. Muscle weakness typically presents from birth to early infancy. Affected infants typically appear *floppy* with hypotonia and poor movements.
3. Muscle weakness may improve, worsen, or stabilize in the short term; however, with time progressive weakness and joint contractures, spinal deformities, and respiratory compromise may affect quality of life and lifespan.
4. Mental retardation ranging from intellectual disability to mild cognitive delay, structural brain and/or eye abnormalities, and seizures are found almost exclusively in the dystroglycanopathies while white matter abnormalities without major cognitive involvement tend to be seen in the laminin-α2-deficient subtype.
5. The main CMD subtypes are: laminin-α2 (merosin) deficiency (MDC1A), collagen VI-deficient CMD, the dystroglycanopathies (caused by mutations in *POMT1, POMT2, FKTN, FKRP, LARGE, POMGNT1, and ISPD*), SEPN1-related CMD (previously known as rigid spine syndrome, *RSMD1*) and LMNA-related CMD (L-CMD). They are grouped by involved protein function and gene in which causative mutations occur.
6. The diagnosis of CMD relies on clinical findings, imaging of brain and muscle, muscle histology (dystrophic features without the structural changes seen in the congenital myopathies), immunohistochemistry of muscle and/or skin and molecular genetic testing.
7. There is no treatment till date.

Chapter 43.8
Congenital Myopathies

Kimberly Amburgey, Michael W Lawlor, James J Dowling

The clinical categorization of congenital myopathies was first introduced by Shy and Magee in 1956. Congenital myopathies are defined by characteristic features observed on muscle biopsy, and the major subtypes include nemaline myopathy, core myopathy, centronuclear myopathy (CNM) and congenital fiber type disproportion (CFTD). Congenital myopathies are a clinically and genetically heterogeneous group of muscle diseases that typically present with hypotonia, motor delay, and muscle weakness. Onset is usually at birth or within the 1st year of life, though patients are diagnosed throughout all pediatric and adult periods. There is a large spectrum of severity, ranging from wheelchair and ventilator dependence to minimal weakness and exercise intolerance. Diagnosis is based on the findings from muscle biopsy, genetic testing, and family history. At present, no curative therapies have been developed, though many are under investigation. There are also few if any disease modifying treatments, and there is a great need for both better understanding and treatment for these often devastating disorders of skeletal muscle.

EPIDEMIOLOGY

Congenital myopathies are estimated at an overall prevalence of 1:22,480–1:26,000 among pediatric patients and 1:28,600–1:135,000 among a combined cohort of pediatric and adult patients. The prevalence of each subtype varies. In several studies, core myopathies were found to be the most prevalent at 1:150,000 for multiminicore disease and 1:249,000–1:170,000 for central core disease. A histopathologic review at the All India Institute of Medical Sciences also found that core myopathies were the most common diagnosis (24% central core disease and 20% multiminicore disease). In one study, the prevalence of CFTD was found to be 1:240,000 and 1:400,000 for CNMs. The prevalence of nemaline myopathy was estimated at 1:179,000–1:1,210,000. Few prevalence studies have been performed; therefore additional studies are needed to further confirm these results.

ETIOPATHOGENESIS

As described below, mutations causing congenital myopathy tend to be in genes associated with the process of muscle contraction, rather than in genes associated with myofiber energy metabolism, stabilization, or repair. The congenital myopathies are named for their histopathologic appearance—myopathies with protein accumulation, cores, central nuclei, and fiber size variation. There are five main subtypes within these groups: (1) nemaline myopathy (including cap disease and zebra body myopathy), (2) core-rod myopathy, (3) core myopathies (including central and multiminicore diseases), (4) CNMs (including myotubular and autosomal centronuclear myopathies), and (5) CFTD. Investigations of the function of genes mutated in congenital myopathies have led to an understanding that abnormalities in a subset of muscle structures and function are the main pathologic drivers of disease in congenital myopathies. In particular, core myopathies and CNMs are associated with abnormalities in the structure and function of the triad (the muscle structure that is responsible for excitation-contraction coupling) and nemaline myopathies are associated with abnormalities in the actin thin filament.

CLINICAL FEATURES

Congenital myopathies are a group of conditions characterized by hypotonia, weakness, and variable respiratory involvement. Onset is typically at birth and the clinical course is usually static or slowly progressive. Inheritance patterns include autosomal dominant, autosomal recessive, and X-linked. Mutations in 18 genes (exhibiting a variety of inheritance patterns within many of these genes) have been associated with multiple subtypes, exemplifying the genetic heterogeneity among these conditions **(Table 1)**.

Clinical Features Associated with Mutations in Specific Genes

When evaluating a child for a suspected diagnosis of congenital myopathy, there are pertinent clinical features that can guide the diagnostic process **(Table 2)**.

Findings associated with skeletal muscle function and metabolism The weakness seen in congenital myopathy can

Table 1 Classification of congenital myopathies

Subtype	Inheritance pattern	Genes
Nemaline myopathy (NM)	AD, AR	ACTA1
	AR	CFL2
	AD	KBTBD13
	AR	KLHL40
	AR	KLHL41
	AR	NEB
	AR	RYR1
	AR	TNNT1
	AD	TPM2
	AD, AR	TPM3
Cap disease (NM Variant)	AD	ACTA1
	AD	TPM2
	AD	TPM3
Zebra body myopathy (NM Variant)	AD	ACTA1
Myosin storage myopathy (hyaline body myopathy)	AD	MYH7
Core-rod myopathy	AD	KBTBD13
	AR	NEB
	AD, AR	RYR1
Central core disease	AD, AR	RYR1
Multiminicore disease	AR	RYR1
	AR	SEPN1
Centronuclear myopathy	AR	BIN1
	AD	CCDC78
	AD	DNM2
	XL	MTM1
	AD	MYF6
	AR	RYR1
	AR	TTN
Congenital fiber type disproportion	AD	ACTA1
	AD	MYH7
	AR	RYR1
	AR	SEPN1
	AD	TPM2
	AD	TPM3

Congenital myopathy subtypes can be further defined by inheritance pattern (AD = autosomal dominant, AR = autosomal recessive, or XL = X-linked) and gene mutation.

Table 2 Key clinical features of congenital myopathy subtypes

Feature	Genetic subtype
Distal muscle weakness	DNM2, MYH7, NEB, TPM2, TPM3
Prominent neck extension weakness (dropped head syndrome)	SEPN1
Malignant hyperthermia	RYR1, STAC3
Exercise induced myalgias	DNM2, RYR1
Orthopedic issues	
Severe arthrogryposis/fetal akinesia	ACTA1, KLHL40, NEB, RYR1, TPM2
Congenital dislocation of the hips	RYR1
Prominent scoliosis	NEB, RYR1, SEPN1
Rigid spine	RYR1, SEPN1
Ophthalmoparesis +/- ptosis	DNM2, MTM1, RYR1
Lower facial weakness/marked bulbar involvement	DNM2, MTM1, NEB, RYR1
Respiratory involvement	
Present at birth	ACTA1, MTM1
Moderate	BIN1, DNM2, RYR1
Out of proportion to muscle weakness	ACTA1, DNM2, MTM1, NEB, SEPN1, TPM3
Cardiomyopathy	ACTA1, DNM2, MYH7, TPM2, TTN
Undescended testes	MTM1, RYR1
Macrosomia	MTM1
Bleeding diathesis, liver, and gastrointestinal complications	MTM1

The presence of specific clinical features can guide genetic testing.

be extremely variable with respect to severity and distribution. While most congenital myopathies present with proximal muscle weakness, predominant distal muscle involvement (as is more typically seen in neuropathies) can been seen with mutations in *DNM2, MYH7, NEB, TPM2,* and *TPM3.* Prominent neck extension weakness (also called dropped head syndrome) is suggestive of a mutation in *SEPN1.* Susceptibility to malignant hyperthermia is an important consideration in some neuromuscular diseases. Malignant hyperthermia is a hypermetabolic response to certain inhaled anesthetics and/or depolarizing muscle relaxants. Among patients with congenital myopathies, a clear association has been linked with mutations in *RYR1* and *STAC3.* Exercise-induced myalgias have been reported in patients with *DNM2* and *RYR1* mutations.

Orthopedic findings Orthopedic issues are a common complaint among patients with congenital myopathies due to a combination of insufficient movement during development and insufficient muscle traction during postnatal skeletal growth. Severe arthrogryposis has been associated with mutations in *ACTA1, KLHL40, NEB, RYR1,* and *TPM2.* Congenital dislocation of the hips (*RYR1*), prominent scoliosis (*NEB, RYR1,* and *SEPN1),* and spinal rigidity *(RYR1* and *SEPN1)* can be suggestive of mutations in specific genes. Patients with *SEPN1* mutations typically develop spinal rigidity prior to scoliosis.

Facial features The "myopathic facies" associated with congenital myopathy is characterized by a long narrow face and open mouth. These facies are reflections of skeletal muscle

weakness during development and growth, and should not be considered deformations or malformations in the classic sense. Ophthalmoparesis, which may be accompanied by ptosis, is suggestive of CNM and/or of mutations in *DNM2, MTM1,* and *RYR1.* Lower facial weakness and bulbar symptoms are seen with most histopathologic subtypes but is often profound in the setting of nemaline myopathy.

Respiratory findings Variable respiratory involvement has been reported across all subtypes. However, onset and severity may provide guidance on further diagnostics. Severe (*ACTA1* and *MTM1*) or moderate *(RYR1, DNM2,* and *BIN1)* respiratory involvement may suggest specific genes. Some patients present with respiratory involvement out of proportion to muscle weakness; this is suggestive particularly of mutations in *SEPN1,* but can also been observed with *NEB, ACTA1,* and *TPM3.*

Cardiac findings While cardiomyopathy is rarely associated with congenital myopathies, it has been reported in patients with *ACTA1, DNM2, MYH7, TPM2,* and, most commonly, with *TTN* mutations. It is important to distinguish those with primary cardiomyopathy versus secondary cardiomyopathy (i.e., cor pulmonale) due to marked respiratory involvement; the latter has historically been described with *SEPN1* mutations.

Other findings Undescended testes have associated with mutations in *MTM1* and *RYR1.* Macrosomia (length above the 90th percentile and large head circumference) is suggestive of mutations in *MTM1.* Bleeding diathesis and liver and gastrointestinal complications have been reported among some patients with myotubular myopathy (MTM) and *MTM1* mutations.

DIFFERENTIAL DIAGNOSIS

There are some key clinical findings that suggest diagnoses other than a congenital myopathy. Increased deep tendon reflexes and/or central nervous system abnormalities are not typically seen in congenital myopathy. That being said, it is important to distinguish primary central nervous system disease from situations where acquired hypoxic ischemic injury has occurred due to respiratory failure from a congenital myopathy. Tongue fasciculations are suggestive of a diagnosis of spinal muscular atrophy (SMA); SMA can have many overlapping clinical features with congenital myopathies, including proximal extremity muscle weakness and reduced/absent reflexes. Dysmorphic features are not typically associated with the congenital myopathies with the exception of King-Denborough syndrome and Native American myopathy. Metabolic abnormalities such as increased lactate or metabolic acidosis are not typically associated with the congenital myopathies. Joint laxity can occur in many patients with congenital myopathies, but if extreme laxity is noted, a diagnosis of a collagen VI myopathy should be considered. There are many overlapping clinical features between congenital myopathies and congenital myotonic dystrophy (cDM1). Genetic testing for cDM1 should always be considered when neonatal hypotonia and weakness are observed, as it is the key alternative diagnosis for congenital myopathies. Of note, mothers of infants with cDM1 may be asymptomatic, but should carry an expanded triplet repeat in the *DMPK* gene.

APPROACH TO DIAGNOSIS

Creatine Kinase

Creatine kinase (CK) is typically normal or mildly elevated (2–3x normal), a distinguishing feature from the congenital muscular dystrophies. However, in some subtypes such as *RYR1*-related myopathies, CK and muscle biopsy may be suggestive of a dystrophic process.

Electromyography/Nerve Conduction Velocities

Electromyography (EMG) will likely show myopathic changes and nerve conduction velocities (NCVs) should be normal, ruling out a neuropathy as a major cause of weakness. Repetitive stimulation [compound muscle action potential (CMAP)] and single fiber EMG are helpful to diagnose and/or distinguish a congenital myasthenic syndrome but may also be useful to identify neuromuscular junction abnormalities in some forms of CNM (*MTM1* and *DNM2*). In these cases, individuals may have the electrodiagnostic features of a myasthenic syndrome and may respond to acetylcholinesterase inhibitors.

Muscle Biopsy

Muscle biopsy provides the diagnostic standard for congenital myopathies, as these disorders are characterized by specific structural abnormalities. It is important to choose the correct muscle to biopsy, as muscles that are unaffected may lack histopathologic features consistent with the diagnosis and end stage muscle may contain mostly fat. Muscle ultrasound or MRI (described below) can be useful to guide the selection of an appropriate muscle to biopsy.

Specific pathological findings on muscle biopsy may narrow down the diagnosis to a group of subtypes and some findings may guide specific genetic testing. It is important to note that while pathological features can guide genetic testing, not all features listed in **Table 3** will be present in every patient.

Nemaline Myopathy

Nemaline myopathy is diagnosed by observing the presence of cytoplasmic protein aggregates called nemaline rods or bodies **(Fig. 1)**. These structures are best identified on modified Gomori trichrome staining and should be confirmed by electron

Table 3 Distinguishing features of congenital myopathies on muscle biopsy

Feature	Genetic subtype
Rods (nemaline bodies)	*ACTA1, CFL2, KBTBD13, KLHL40, KLHL4, NEB, RYR1, TNNT1, TPM2, TPM3*
Rods confined to type I fibers	*TPM3*
Intranuclear rods	*ACTA1*
Caps	*ACTA1, TPM2, TPM3*
Zebra bodies	*ACTA1*
Hyaline bodies	*MYH7*
Cores	*MYH7, RYR1, SEPN1*
Central cores	*RYR1*
Minicores	*RYR1, SEPN1*
Cores and rods	*KBTBD13, NEB, RYR1*
Central nuclei	*BIN1, CCDC78, DNM2, MTM1, MYF6, RYR1, TTN*
Marked myofiber atrophy and large central aggregates of mitochondria and glycogen	*MTM1*
Radial strands	*DNM2*
Necklace fibers	*MTM1, DNM2*
Fiber type disproportion	*ACTA1, MYH7, RYR1, SEPN1, TPM2, TPM3*
Marked type I fiber predominance (>90%)	*RYR1*

The presence of specific pathological features can guide genetic testing.
Figure 1 Pathological findings on muscle biopsy in congenital myopathy. The characteristic pathology of nemaline myopathy (NM), centronuclear myopathy due to *DNM2* mutation (CNM), X-linked myotubular myopathy (XLMTM), central core disease (CCD), multiminicore disease (MMC) and congenital fiber type disproportion (CFTD) are shown. The top row of images all shows staining with hematoxylin and eosin (H&E). Special stains related to the diagnosis of each disease are shown in the bottom row of images, including Gomori trichrome (Gomori), NADH, and an ATPase stain performed at pH 9.4 (which stains the type 2 fibers darkly and the type 1 fibers lightly). Bar = 40 μm

microscopy (EM), if possible. The number of rods and percentage of fibers with rods do not correlate with disease severity, and a variety of abnormalities of contractile function (including altered thin filament length and abnormal calcium utilization) and variable degrees of myofiber smallness (hypotrophy) have been found in muscles harboring nemaline myopathy. Nemaline myopathy is caused by mutations in at least 10 genes, many of which encode the sarcomeric thin filament **(Table 1)**. Nemaline rod distributions in certain configurations can be suggestive of causative genes, including *TPM3* (rods and hypotrophy only seen in type 1 myofibers), *ACTA1* (intranuclear rods), and *TPM2* (cap-shaped subsarcolemmal aggregates of rod-like material). Some nemaline rod/body variants, such as zebra bodies composed of stacks of thin filament material, can be seen and suggest an *ACTA1* gene mutation.

Core Myopathies

Cores are areas devoid of mitochondria and therefore, lack oxidative enzyme activity **(Fig. 1)**. These areas are frequently associated with condensed areas of contractile apparatus, so they often retain their myosin ATPase reactivity. Central cores and minicores are best identified on oxidative stains, nicotinamide adenine dinucleotide dehydrogenase (NADH) and succinate dehydrogenase (SDH). As there is considerable genetic overlap between the *RYR1* and *SEPN1* mutations that cause central core and multiminicore disease, the pathological distinction between these structures is no longer as critical as it once seemed. Central cores are large, single structures that are longer than they are wide, and minicores are usually smaller structures that only span a few sarcomeres and in which several can be seen in a single transversely-sectioned myofiber. Cores may look similar to targetoid lesions (typically a neurogenic finding) or areas of reduced staining (central pallor), therefore it is important to confirm with EM when possible. Some cases of core myopathy due to *RYR1* mutations can show an exceptional degree of type 1 fiber predominance (> 90%).

Core-Rod Myopathy

Core-rod myopathy is characterized by the presence of both cores and rods on biopsy. EM is vital to confirm the presence of both rods and cores, especially given that nemaline rod aggregates may displace mitochondria to provide the appearance of cores on oxidative stains.

Centronuclear Myopathies

It is important to distinguish central nuclei from internalized nuclei. Internalized nuclei are typically associated with regenerating/regenerated myofibers, myotonic dystrophy, or even normal fibers in the area of a myotendinous insertion site. The relevance of central nucleation to the production of weakness is debatable and it is potentially just an easily recognizable indication of organelle mislocalization that is frequently observed in these diseases. Myofiber hypotrophy and disorganization and loss of triad structures on EM also occur to varying degrees across the several genetic causes of CNM. The clinical history and pattern of organelle mislocalization can be very useful in identifying the causative gene. A severe neonatal phenotype with marked myofiber smallness and large central aggregates of mitochondria and glycogen strongly suggests an *MTM1* mutation. In contrast, a less severe phenotype and the presence of radial strands (spokes on a wheel) on oxidative stains and/or PAS are suggestive of a *DNM2* mutation. Necklace fibers (rings of mitochondria and glycogen connecting to an internalized nucleus) have been identified in some cases of CNM. These may be suggestive of a female carrier of an *MTM1* mutation, late-onset MTM in males, or *DNM2* mutations.

Congenital Fiber Type Disproportion

Congenital fiber type disproportion represents a specific pattern of myofiber hypotrophy that can be seen across the entire range of congenital myopathy **(Fig. 1)**, and includes moderate to severe hypotrophy of type 1 fibers in the biopsy (type 1 fibers > 25% smaller than type 2 fibers), often occurring in combination with type 1 fiber predominance (>55% of fibers are type 1 fibers). The presence of this pattern in association with nemaline rods, excessive central nucleation, or core structures would yield diagnoses of nemaline myopathy, CNM, and core myopathy, respectively. When these specific structures are not present, however, this pattern of hypotrophy is diagnosed as CFTD. Some patients with CFTD may later be re-classified as other congenital myopathies due to the presence of additional pathological findings on repeat biopsies. The presence of CFTD pathology without additional pathological findings is most commonly associated with mutations in *TPM3*. Particularly marked fiber type disproportion (>90% type 1 fibers) has been seen with mutations in *RYR1*.

Muscle MRI

Muscle MRI is a noninvasive method for identifying affected muscle groups. The procedure is relatively quick and well tolerated by many children, and most do not require anesthesia for the procedure. MRI can identify patterns of affected muscle groups associated with specific gene mutations **(Table 4)**. According to Quijano-Roy and colleagues (2011), proximal versus distal weakness and the involvement or sparing of the tibialis anterior and soleus are the most helpful in guiding genetic diagnosis. Even if a specific pattern is not identified, muscle MRI can help guide the site for muscle biopsy. It is important to biopsy a muscle that is affected, but not end stage.

Muscle Ultrasound

Muscle ultrasound is another method that may guide genetic testing using patterns of muscle involvement and selection of muscle for biopsy. Similar patterns as to what can be observed with MRI are seen with ultrasound. However, the procedure is highly dependent on ultrasonographer's expertise.

Genetic Testing

Specific clinical features and/or results of muscle MRI and/or biopsy may guide genetic testing selection **(Tables 2 to 4)**. If there are specific or diagnostic findings, single gene sequencing (Sanger and/or next generation) may be the most cost-efficient method for confirming the diagnosis. However, most often the clinical picture and muscle biopsy do not point to a single genetic cause, or patients may want to avoid an invasive procedure such as a muscle biopsy. Therefore, the most cost effective and least invasive diagnostic testing strategy may be a congenital myopathy next generation sequencing (NGS) gene panel. Several panels are currently available clinically by multiple companies. There are several considerations when choosing a panel: (1) Mutation type, (2) gene coverage, and (3) pricing. It is important to consider whether the testing includes parental testing of variants of unknown significance, Sanger confirmation of variants identified and/or areas of low coverage are backfilled with Sanger sequencing, and deletion/duplication testing.

Recent publications point to some of the drawbacks of NGS panels in diagnosing neuromuscular disorders. NGS can detect sequence variations and small insertions/deletions (indels), however, it cannot detect repeat expansions or complex structural variants. Additionally, some areas have consistently low coverage (typically < 20X) due to sequence complexity, problematic library synthesis, and unusual GC content. Valencia and colleagues

(2013) identified multiple genes (*COL6A1, COL6A2, COL6A3, FKTN, ITGA7, LAMA2, POMT1, POMT2, SEPN1*) with consistently low coverage using a congenital muscular dystrophy NGS panel. NGS also has a high error rate compared to Sanger sequencing. Artificial mutations are produced during template amplification or sequencing. Therefore, all variants identified by NGS must be confirmed by Sanger sequencing. Lastly, panels identify variants of unknown significance in genes that may not have otherwise been tested. It is important to interpret variants in the context of the patient's phenotype. It may be helpful to compare the variant to published mutation types and location to help in predicting the pathogenicity of the variant.

MANAGEMENT

Medical management of patients with congenital myopathies should include a multidisciplinary team including the following specialties: neurology, pulmonology, orthopedics, rehabilitation specialists, gastrointestinal/nutrition, and genetics. Depending on the specific subtype, ophthalmology and cardiology may need to be involved. Details of specific standard of care guidelines can be found in the publication by Wang and colleagues (2012).

Specific management guidelines are available for some subtypes. For nemaline and centronuclear myopathies, speech, feeding, and secretion management will be needed. Additionally, many patients with nemaline and centronuclear myopathies may need respiratory support, in particular patients with *ACTA1, BIN1, DNM2, MTM1, NEB, RYR1,* and *TPM3* mutations. Respiratory management will be particularly important for patients with *SEPN1* mutations. CNM patients with ptosis may benefit from surgical management. Orthopedic management of scoliosis will be important for patients with *NEB, RYR1,* and *SEPN1* mutations. Cardiac screening should be initiated in patients with *ACTA1, DNM2, MYH7, TPM2,* and *TTN.* Malignant hyperthermia precautions are needed for patients with *RYR1* mutations.

No curative therapies are currently available for the congenital myopathies; however, several therapies are under investigation. These include L-tyrosine for nemaline myopathy. L-tyrosine may improve bulbar function, energy levels, and exercise tolerance. Neuromuscular junction abnormalities have been identified in animal models and patients with CNM/MTM and treatment with an acetylcholinesterase inhibitor, such as Mestinon, has

been reported to improve some symptoms. Gene and enzyme replacement therapies are currently being developed for patients with MTM. Oxidative stress has been identified in *SEPN1* and *RYR1*-related myopathies. Treatment with antioxidants, such as N-acetylcysteine (NAC), has reduced oxidative stress in animal models and patient myotubes. Clinical trials for both myopathies using NAC treatment are currently underway. Additional therapies are under investigation for many congenital myopathy subtypes.

IN A NUTSHELL

1. Key clinical features and diagnostic testing results can narrow the differential for congenital myopathy subtypes.
2. Specific management guidelines should be considered when treating patients with different subtypes.

Chapter 43.9
Neuromuscular Transmission Disorders
Venkateswaran Ramesh

PHYSIOLOGY OF NORMAL NEUROMUSCULAR TRANSMISSION

Depolarization in a motor neuron results in propagation of action potentials to the motor end-plate. This triggers opening of voltage-gated calcium channels in the presynaptic membrane terminals, which in turn triggers release of the chemical neurotransmitter acetylcholine. Acetylcholine diffuses across the synaptic cleft and binds to receptors at the postsynaptic membrane, giving rise to end-plate potentials via opening of sodium channels in the skeletal muscle membrane. The amplitude of the end-plate potential must exceed a critical threshold in order to cause depolarization of the skeletal muscle cell and contraction of the myocyte. A nerve impulse causing release of a large number of quanta of acetylcholine can induce depolarization of a large number of myocytes in the motor unit, which summate to generate a compound muscle action potential (CMAP) and muscle contraction. Acetylcholine remaining in the synaptic cleft is removed by hydrolysis catalyzed by the enzyme acetylcholinesterase (AChE), terminating the action potential and preventing overcontraction of the myocyte **(Fig. 1)**.

Myasthenia is fluctuating muscle weakness and fatigability on exercise due to a group of heterogeneous disorders of neuromuscular junction transmission. There are both congenital and acquired forms. The main etiologies are autoimmune and genetic.

ACQUIRED MYASTHENIC SYNDROMES

The classical clinical syndrome of disordered neuromuscular junction transmission is myasthenia gravis (MG), an acquired autoimmune antibody mediated postsynaptic disorder that is uncommon in childhood and may be seen in adolescents. MG has a prevalence of 5/100,000. It has a bimodal incidence being most common in women in their 2nd and 3rd decade of life and men in the 6th and 7th decade.

Pathogenesis
The disease is due to circulating antibodies to acetylcholine receptors (AChR), which bind to the receptor at the neuromuscular junction and prevent a normal action of acetylcholine in opening the calcium channel in the muscle fiber. About 80% of cases show antibodies to the AChR. A minority is positive for muscle specific kinase (MuSK) antibodies (10–12%). The disorder can be associated with thymic hyperplasia and tumors.

Clinical Features
Fatigable weakness may be generalized or confined to a specific group of muscles. Onset is insidious over weeks and months, often during the course of an intercurrent illness, and patients may show diurnal variation of fatigability and weakness. Periorbital muscles are often involved with ptosis that worsens during the day with diplopia in the evening. Weak facial, tongue and pharyngeal muscles can cause difficulty chewing, dysphagia and flaccid dysarthria. The disease may be confined to the eye muscles in younger patients. In older patients, bulbar symptoms are often associated. Weakness of limb movement tends to occur later in the disease and results in tiredness, fatigue on exertion and inability to sustain exercise. Deep tendon reflexes are normal. The course of the illness is variable. Symptoms may be more pronounced at times of emotional and physical stress. Diagnosis depends on demonstration of fatigable weakness in levator palpebrae superioris or limb muscles.

LAMBERT-EATON MYASTHENIC SYNDROME

This is a rare acquired neuromuscular junction transmission disorder first described in 1957. It can be further classified as cancer associated Lambert-Eaton myasthenic syndrome (Ca-LEMS), most often (>60%) seen as a paraneoplastic disorder with small cell carcinoma of the lung, though can be associated with other malignancies including non-Hodgkin lymphoma and leukemia, and non-cancer associated/autoimmune (NCa-LEMS). It is an autoimmune disorder with antibodies directed against presynaptic voltage-gated calcium channels in 85% patients. Onset is subacute with proximal muscles of lower limbs and shoulder most often affected. Involvement of cranial musculature is uncommon. Patients may improve transiently with exercise. Electromyography (EMG) study with tetanic stimulation shows facilitation in the size of the muscle action potential in contrast to decremental response seen in classical MG.

CONGENITAL MYASTHENIC SYNDROME

When symptoms and signs of myasthenia are of congenital or early childhood onset (< 2 years of age), it is defined a *congenital myasthenic syndrome (CMS)*. They may go unrecognized into adolescence and adulthood. It is often seen in a familial setting. The disease is rare with an incidence of less than 1 in 200,000 patients. CMS is a heterogeneous group of disorders, arising due to

1. Impulse arrives at the motor end plate causing release of Ach from vesicles in the axon terminus

Ca^{+2}

Ca^{+2} acts as an intermediate in causing exocytosis by Ach vesicles

2. ACH diffuses across the synapse to bind to receptors on the sarcolemma

ACH receptors (chemically regulated ion gates)

3. Binding of ACH to the receptors causes Na+ to enter the cell causing depolarization.

Polarized sarcolemma, produced by the sodium-potassium pump

4. If threshold depolarization occurs a new impulse (action potential) moves along the sarcolemma

5. Sarcolemma repolarizes:
   (a) K^+ leaves cell
   (b) Na/K pump restores polarity

6. ACH broken down by ACH-E (ACHase, cholinesterase).

Figure 1 Physiology of normal neuromuscular transmission

genetic mutations causing critical change in presynaptic, synaptic or postsynaptic proteins, leading to impaired neuromuscular junction transmission and rarely a chronic myopathy. The calcium dependent release of acetylcholine from the nerve terminals and the efficiency of released quanta generating a postsynaptic depolarization determine the efficiency of neuromuscular transmission. Symptoms persist throughout life and may respond to anticholinesterases.

Classification

A conceptual framework for understanding CMS is to classify them by site, as presynaptic, synaptic or postsynaptic and the molecular basis of the neuromuscular transmission defect **(Table 1)**. Genes responsible for the pathology at various levels are depicted in **Figure 2**.

Presynaptic syndromes The causative mechanisms involve the synthesis or packaging of acetylcholine quanta into synaptic vesicles. The most important and typical presynaptic defect is deficiency of choline acetyl transferase (ChAT), a rate limiting enzyme responsible for the synthesis of acetylcholine, resulting in decreased release of acetylcholine quanta. ChAT is found in high concentration in cholinergic nerve terminals and is encoded by the ChAT gene. Presynaptic defects are the least common of the CMS and account for about 6% of CMS.

Synaptic syndromes There is congenital deficiency of AChE localized on the end plate on the muscle surface. AChE breaks down acetylcholine and is found mainly at neuromuscular junction and brain cholinergic synapses. Its activity is to terminate synaptic transmission. It accounts for up to 15% of CMS.

Postsynaptic syndromes These are due to defects of the AChR (including the expression, aggregation or kinetic properties) and are the most common cause of CMS accounting for 70% of patients. Slow channel and fast channel syndromes also belong to this group. Reduced AChR expression can also be caused by defects of essential muscle intrinsic proteins *viz.* receptor-associated protein at the synapse (RAPSYN), MuSK and *DOK-7*. The latter has been identified as a cause of limb-girdle myasthenia.

Clinical Features

These children present with weakness of ocular, periorbital, facial, bulbar and respiratory muscles, worsened by exertion (crying, feeding and other activity). Babies can present with generalized floppiness. Weakness of extraocular and bulbar muscles results in ptosis, feeding difficulties, weak cry, and developmental milestones may be normal or delayed **(Fig. 3)**. Symptoms may progress during adolescence.

Symptoms can be episodic with severe weakness and respiratory insufficiency occurring during intercurrent illness with fever, excitement or without. Sudden critical weakness of bulbar and respiratory muscle weakness causing apnea and respiratory arrest is a critical symptom and hypoxic cardiac arrest can follow. CMS should be considered when infants and young children present with acute life-threatening events (ALTE) or

Table 1 Congenital myasthenia syndromes

Presynaptic defects (6%)
CMS with episodic apnea: Defect of choline acetyltransferase (ChAT)
Floppy and weak; extraocular, bulbar and respiratory muscles affected
Cardinal feature is episodic life-threatening apneas
Autosomal recessive (AR)

Synaptic defects (14%)
End-plate acetylcholinesterase (AChE) deficiency (AR)

Postsynaptic defects (70%)
Primary AChR deficiency with or without kinetic abnormality
Slow-channel syndrome AR
Fast-channel syndrome AR
Receptor-associated protein at the synapse (RAPSYN) deficiency
Sodium channel myasthenia

Defects in mechanisms of end-plate development and maintenance (10%)
DOK-7 myasthenia

Figure 2 Genes responsible for congenital myasthenia syndromes (as at 2014)

Figure 4 Tensilon (edrophonium test): A positive test is immediate elevation of both upper eyelids with resolution of ptosis after about a minute and lasting about 5 min

severe apneas. This is a particularly prominent feature of ChAT deficiency. Affected children may be well in-between episodes.

Neonatal myasthenia gravis Transport of AChR receptor subunit antibodies across the placenta can cause transient neonatal MG in up to 15% of infants born to mothers affected by autoimmune myasthenia. Ptosis, facial weakness, poor feeding, weak cry and respiratory insufficiency are present from birth. Cord blood sample should be taken at delivery to measure AChR receptor antibodies. Respiratory function and feeding must be carefully monitored in the infant. Symptoms and signs resolve by 3–4 weeks of age.

In older children and adolescents with myasthenic symptoms, both autoimmune myasthenia and CMS should be sought, initially with tests seeking antibodies against AChR or MuSK antibodies. During clinical examination, an important clue is muscle fatigue and weakness on sustained exertion that can be demonstrated by worsening ptosis during sustained upward gaze or measuring arm elevation or deep knee bends. Ocular muscle involvement may be absent or mild in some cases of AChE deficiency, the slow channel syndrome, receptor-associated protein of the synapse (*RAPSN)* deficiency or limb-girdle myasthenia caused by mutations in *DOK-7* or other genes. Deep tendon reflexes are often preserved though patients may be hyporeflexic.

INVESTIGATIONS IN SUSPECTED MYASTHENIA

Bedside Tests

Icepack test is an easily performed bedside test to seek support for the diagnosis of myasthenia. An icepack is held firmly over one eye (the test eye) for 2 min. Improvement in the ptosis, i.e., better elevation of the test upper eyelid relative to the opposite eye (control), suggests myasthenia as the cause of ptosis. This test relies on the fact that surface cooling of the muscle improves neuromuscular junction transmission.

Tensilon (edrophonium bromide) test shows rapid and transient resolution of symptoms and confirms myasthenia. Edrophonium is a short-acting anticholinesterase drug with rapid onset of action. This test should be done with placebo-control and ideally with an independent second observer and if possible video recording. There is a small risk of muscarinic side effects. Patient's heart rate and blood pressure have to be monitored with atropine being available (0.02 mg/kg/dose IV, maximum 2 mg). The test dose

of edrophonium 20 mcg/kg is given intravenously with a normal saline control. If there is no adverse effect within the 1st min, the rest of edrophonium 80 mcg/kg/dose (maximum total dose of 10 mg) is given. A positive test is immediate elevation of both upper eyelids with resolution of ptosis after about a minute and lasting about 5 min **(Fig. 4)**. A negative test does not exclude the diagnosis.

Serological Tests

Serum AChR antibodies are highly specific for MG and occur in 85% of those with generalized disease and 50% of those with ocular disease. Patient who are negative for AChR antibodies are referred to as *seronegative*. A subgroup of these patients are positive for MuSK antibodies. MuSK antibodies can be associated with MG in childhood (5–10%) and tend to be associated with a more refractory and severe disease course. Serological test for AChR antibodies and MuSK antibodies are negative in most patients with genetically determined CMS. The exception is neonatal onset MG, due to transplacental transfer of maternal AChR antibodies.

Myasthenia gravis is seen in association with autoimmune thyroid disease in 10% of patients. Thyroid function tests should be done in all patients. MG patients have increased incidence of familial autoimmune disease. HLAB8 and DR3 in young women and DR2 in older men are often associated.

Electromyography in Neuromuscular Disorders

In suspected neuromuscular junction disorders electrical activity of muscles (EMG) from a number of weak muscles may be recorded with surface electrodes, concentric needle electrodes and microelectrode needles in single fiber studies, the latter particularly for studies of neuromuscular transmission. The electrical activity recorded from normal muscles varies depending on the state of the muscles. Normal muscle is electrically silent when fully relaxed unless placed close to an end-plate region; following insertion or movement of a needle electrode, a short burst of activity lasting 2s or 3s may occur. Leading muscle activity motor unit potentials are recorded. The activity recorded from each single motor unit, i.e., a motor neuron and all the muscle fibers is the sum of the activity from those muscle fibers within the unit that are close to the needle. All motor unit potentials are usually bi- or triphasic with duration up to 15 ms and amplitude of up to 3 microvolts.

Any abnormality of diseased muscle during activity is best considered in terms of morphology of motor units and changes in recruitment pattern. The shape, amplitude and duration of motor unit potentials are determined by the compound activity of muscle fibers within that unit. In myopathic disorders, smaller amplitude shorter duration potentials are obtained due to loss of muscle fibers in the motor unit. In patients with MG or the myasthenic syndromes, minor abnormalities in EMG may be present. Motor unit potentials may be variable in amplitude and configuration and this change can be subtle. In MG, tetanic train (serial rapid)

Figure 5 Infant having needle EMG recorded from right orbicularis oculi with repetitive nerve stimulation (RNS) of facial nerve
Figure 6 Surface EMG recorded from abductor pollicis brevis with tetanic train stimulation of median nerve at the wrist. Note reduction in compound muscle action potential (CMAP) amplitude from first and fourth responses

stimulation on EMG reveals progressive reduction in size of successive motor action potentials.

Confirmation of a clinical diagnosis of myasthenia needs recurrent nerve stimulation (RNS) of the motor nerve **(Fig. 5)** and recording of evoked CMAP. In children, this can be done relatively easily by stimulating the ulnar nerve and recording from the abductor digiti minimi, or the median nerve and recording from the abductor pollicis longus **(Fig. 6)**.

Short tetanic trains of 1–10 Hz, will not cause significant decrement in the size of evoked CMAP in normal individuals. EMG with repetitive nerve stimulation (RNS) shows decremental response of the CMAP amplitude at low frequency (2–3 HZ) in 65–80% patients. Its absence does not exclude the diagnosis.

Single fiber EMG (SFEMG) studies These are very helpful for detecting abnormalities of neuromuscular transmission. If a needle with one or more small recording electrodes along its length is inserted into muscle, it may be possible to position it so that recordings can be made from two or more single muscle fibers within a motor unit. When the muscle is contracted, individual fibers

will be activated with close temporal association. The activation of fibers should have a relatively fixed temporal relationship with little *jitter* (i.e., little variation in latency of activation of fibers) and no blocking (i.e., no absence of individual fiber activity). In disorders of neuromuscular transmission there is greatly increased jitter and evidence of neuromuscular block between the first and fourth or the first and fifth responses. Single fiber EMG studies look for failed or delayed conduction in pairs of muscle fibers supplied by a single nerve fiber. There is increased jitter or blocking. These findings occur in 90% cases of patients with generalized MG and smaller but significant proportion of CMS (60%).

Other Studies

The clinical and EMG phenotype of many genetically determined CMS is distinct. Targeted mutation screening for distinct and known clinical and EMG phenotypes, e.g. ChAT should be performed. Approximately 10% of patients with MG are found to have thymic tumors or hyperplasia, particularly older men, who should have chest CT/MRI with contrast.

TREATMENT OF ACQUIRED MYASTHENIC SYNDROMES

Myasthenia gravis responds to therapy with anticholinesterase drugs which slow the breakdown of acetylcholine at the neuromuscular junction. The usual agent used is pyridostigmine 30 mg to 60 mg 4 hourly in adults and 1–1.5 mg/kg/day in children under age 12 years. It has slower onset and longer duration of action with milder gastrointestinal effects than neostigmine. Atropine (0.6 mg twice daily) or probanthine is added to the regime to block unwanted muscarinic and autonomic effects of the anticholinesterases like colic and diarrhea.

Steroids reduce the effect of the disease and in patients with purely ocular myasthenia may be the most effective therapy. Steroids can be used in short courses with doses of 10 mg to 20 mg daily or on alternate days with maximum 2 mg/kg. Weaning from steroids should be slow with maintenance at the lowest possible dose.

In acute severe life-threatening myasthenia, plasmapheresis may give significant benefit; however, regular plasmapheresis does not appear to play a role in standard therapy of the disease.

If a thymic tumor or hyperplasia is detected, thymectomy is the treatment of choice although patients may take months to show benefit from the procedure. This is always indicated in patients with thymoma. Thymectomy also gives excellent results in patients who are AChR positive.

Infants with transient neonatal MG respond to anticholinesterase medication with resolution by 3–4 weeks of age. Steroid sparing agents such as azathioprine, methotrexate and mycophenolate are used in chronic MG. Rarely patients may need plasmapheresis or intravenous immunoglobulin infusions.

When MG patients on treatment deteriorate, it is important to determine if it is a cholinergic crisis due to excessive treatment or a myasthenic crisis due to inadequate and ineffective therapy. It is best to admit the patient, discontinue all therapy and observe the condition over a few days.

In LEMS, anticholinesterase medication is not helpful. Therapy with 3,4-diaminopyridine is beneficial. Plasmapheresis and intravenous immunoglobulin (IVIG) also have benefit.

TREATMENT OF CONGENITAL MYASTHENIC SYNDROMES

Except in a minority, anticholinesterase medications also benefit patients with CMSs. Pyridostigmine in doses of 1–1.5 mg/kg body

weight is usually used at a dosing frequency 3–4 hourly with fewer side effects. Prophylactic anticholinesterase therapy should be given to patients even if they are well between crises. Parents should be advised and warned about worsening of symptoms during intercurrent illness and fever with possible life-threatening respiratory arrests that may lead to hypoxic cardiac arrest. Parents must be trained in basic resuscitation and given bag and mask equipment for helping the child during a crisis during transport to hospital. In a minority of CMS cases, 3,4-diaminopyridine can be used in treatment.

Special precautions during anesthesia Particular care needs to be taken during any anesthetic procedure in all patients with myasthenia. Avoidance of neuromuscular blocking drugs is vital to ensure patient safety at this time. Certain drugs, such as aminoglycoside antibiotics (neomycin, streptomycin) and some tetracyclines and D-penicillamine, can worsen myasthenic weakness. The last mentioned drug may also independently produce a myasthenic syndrome.

PROGNOSIS

In a large number of patients with CMS, the disease becomes milder in their teens and adulthood.

IN A NUTSHELL

1. Myasthenia is fluctuating muscle weakness and fatigability on exercise due to a group of heterogeneous disorders of neuromuscular junction transmission. There are both congenital and acquired forms. The main etiologies are autoimmune and genetic.
2. Acquired myasthenia is due to circulating antibodies to AChRs, which bind to the receptor at the neuromuscular junction and prevent a normal action of acetylcholine in opening the calcium channel in the muscle fiber.
3. Congenital myasthenic syndrome(s) arise due to genetic mutations causing critical change in presynaptic, synaptic or postsynaptic proteins, leading to impaired neuromuscular junction transmission. The calcium dependent release of acetylcholine from the nerve terminals and the efficiency of released quanta generating a postsynaptic depolarization determine the efficiency of neuromuscular transmission. AChR and MuSK antibodies are absent.
4. Transport of AChR receptor subunit antibodies across the placenta can cause transient neonatal MG in up to 15% of infants born to mothers affected by autoimmune myasthenia.
5. Most patients with acquired or congenital myasthenia respond to therapy with anticholinesterase drugs.

Chapter 43.10
Hereditary Motor and Sensory Neuropathies

V Viswanathan

Hereditary motor and sensory neuropathy (HMSN) are a genetically heterogeneous group of disorders with variable ages of presentation. The typical patient has progressive distal weakness mild to moderate sensory loss, depressed or absent tendon reflexes and high arched feet. Four major categories of HMSN have been described although each of these are further categorized based on molecular and linkage analysis. The terms Charcot-Marie-Tooth (CMT) disease and hereditary sensory and motor neuropathy are interchangeable. The exact prevalence of the disorder is unknown although it is said to occur in 36 in 100,000 persons.

The genetic defect results in structural/functional deficiencies in axons or myelin sheath of the nerves and that causes the clinical features that we see. The primary demyelinating neuropathies are CMT1, CMT3 and CMT4 and primary axonal neuropathies CMT2. However, the classification of these varieties is not that rigid and many times the pathologies are intermingled due to the close interaction between the Schwann cells and the neurons.

The disease is named after the people who classically described it: Jean-Martin Charcot (1825–1893) and his pupil Pierre Marie (1853–1940) and Howard Henry Tooth (1856–1925) (*Peroneal type of progressive muscular atrophy, dissertation*, London, 1886).

CLASSIFICATION

The initial classification of these disorders was done by Dyck and Lambert in 1968 as HMSNs, the hereditary sensory and autonomic neuropathies and the hereditary motor neuropathies. Harding and Thomas further subdivided the HMSN in a group with motor nerve conduction velocity (mNCV) below 38 m/s (HMSN-type 1) and a group with mNCV above 38 m/s (HMSN-type II). The present classification takes into account the clinical, electrophysiological, pathological and genetic criteria for the classification **(Table 1)**. As molecular genetics becomes more advanced over the recent years there are over 50 chromosomal loci described for HMSN and 33 genes with mutations causing HMSN including 24 phenotypic forms of dominant motor and sensory neuropathy. Mutations in

Table 1 Current classification of Charcot-Marie-Tooth disease and related neuropathies

Neuropathic type	Key neuropathic features
CMT 1	Dominantly inherited with low NCV
CMT 2	Dominantly inherited with normal or low normal NCV
CMT X	X-linked inherited
HNPP	Dominantly inherited with focal nerve lesions
Dejerine Sottas syndrome	Variable inheritance with extremely low NCV and severe disability
Congenital hypomyelination	Sporadic inheritance with extremely low NCV and extremely severe disability
CMT 4	Recessively inherited CMT

Abbreviations: CMT, Charcot-Marie-Tooth; NCV, nerve conduction velocities; HNPP, hereditary neuropathy with liability to pressure palsies.

four genes (*PMP22, GJB1, MPZ* and *MFN2*) cause more than 90% of the genetically identifiable cases of CMT in North America.

There are rare types of HMSN described with associated corpus callosal agenesis suggesting that sometimes you can get gene defects causing structural and neuro-degenerative problems in the same child with early onset of developmental issues.

CLINICAL FEATURES

The age of onset is within the first or second decade of life although it has been reported to be as late as seventh decade. The children present typically with slowly progressive difficulty with walking/running and frequent tripping/falls. The gait is usually a high stepping gait due to the weakness and wasting is seen in the distal muscles of the legs. Most patients develop high arched feet and clawing of the toes with thinning of the calf muscles noticed by the parents **(Fig. 1)**. The disease later progresses to involve the hands and forearms resulting in difficulties with writing and manipulating small objects **(Fig. 2)**.

In all cases, distal usually symmetrical sensory deficits-stocking or glove distribution are present but very often not noticed by the child/family. The weakness and atrophy is predominant in the peroneal group of muscles in the legs and the small muscles of the hand and feet. The tendon reflexes are diminished or absent especially in the ankle. Wasting of the foot and distal lower extremity muscles develop over time and may produce the classical *inverted champagne bottle* appearance. In the demyelinating forms of HMSN, nerve hypertrophy may be visible and thickened nerves such as the greater auricular nerve may be palpable. The course of the disease is often insidious and most patients do not or only late in life become wheelchair dependent.

Charcot-Marie-Tooth Disease 1

This is an autosomal dominant form of demyelinating neuropathy and accounts for about 50% of all cases. There are four different variants described depending on the genetic abnormality and the subtypes are clinically indistinguishable. Family history is usually present. Although the clinical features may start in childhood with pes cavus, weakness of peroneal group of muscles and diminished tendon jerks, this does not cause severe disability in childhood. Eventually after the age of 20 years, the weakness spreads to the proximal muscles of the legs and hands. Scoliosis is unusual. Cramps with exercise may occur. Position sense

Figure 1 Pes cavus foot deformity

Figure 2 Claw hand deformity

becomes impaired in the fingers and toes. Hip dysplasia may be an associated feature.

Charcot-Marie-Tooth Disease 2

The clinical phenotype is similar to CMT 1 except that the nerve conduction velocity (NCV) in this condition is normal or near normal. This also has an autosomal dominant inheritance pattern. There are seven different subtypes described depending on the chromosomal locus. These patients have less sensory loss as compared to CMT 1. The progression of symptoms is typically slow and disability does not occur until middle adult life. Prominent vocal cord and respiratory paralysis (intercostals and diaphragmatic) occurs in CMT 2C. In CMT 2D prominent weakness and atrophy of the hands has been reported.

Charcot-Marie-Tooth Disease 3

Dejerine Sottas Disease

This is a severe type of demyelinating neuropathy of infancy and childhood associated with slow NCV, elevated cerebrospinal fluid protein, marked clinical weakness and hypertrophic nerves with onion bulb formation.

Charcot-Marie-Tooth Disease 4

The inheritance pattern for this group is autosomal recessive. Based on the genetic locus and the protein that is deficient, this has been further subdivided into seven different types. The clinical features of distal muscle weakness start by around the second year of life and progress to involve the proximal muscles by about 10 years of age. They may have associated mild sensory loss, absent deep tendon reflexes and skeletal deformities. Scoliosis appears as age advances. The nerve conduction studies in these children show severe demyelinating type of neuropathy with marked reduction in the NCV to around 15–17 m/s.

Charcot-Marie-Tooth Disease X (CMTX)

This is an X-linked dominant condition. The mutations are specifically in the connexion 32 gene. The males are affected primarily while the females are only mildly affected or asymptomatic. The clinical features are very similar to CMT 1A although more severe. The symptoms develop during the first decade and then slowly progress over a period of time. The initial clinical features are very similar to the other types with foot drop and absent tendon reflexes with mild to moderate sensory loss in the feet. Hearing loss has been described with this condition.

NEUROPHYSIOLOGY

Marked slowing of NCV is the hallmark of CMT 1. Harding and Thomas found that median motor NCV of 38 m/s was a useful value in separating the demyelinating variety of CMT 1 and the axonal CMT 2. The conduction slowing was evident in children with CMT 1 by the age of 2 years and appeared to progressively drop over time, stabilizing by about 5 years of age. A reduction in the compound muscle action potential was also an early finding, present in recording from the foot in 50% of the children by the age of 5 in CMT 1. Weakness does not appear to correlate with the NCV. Conduction velocity changes very little over many years despite progressive neurologic disability.

MANAGEMENT

The management is mainly supportive. No specific treatment is available. Early in the course of the disease regular strengthening exercises for the feet and legs with active stretching of the feet may be beneficial. The most important aspect of care is the care for the feet and prevention of early deformities. Regular/gentle stretching at the ankles/feet may be of considerable benefit in helping the maintain gait and prevent early onset of foot drop. Use of well made, light weight, ankle foot orthosis (AFO) with good lining of cushion/padding to prevent rubbing/ulceration in the feet is important. These can be made in such a way that it slips into the shoes so that the child is able to walk and take care of his day-to-day activities comfortably. The AFOs need to be periodically checked and adjusted/a new one made as the children grow and many times they become too small/too tight and uncomfortable for the children to wear them. Do remember that these children also have some sensory loss in the feet and so they are liable for trophic ulcers in the feet and these need to be looked for when you examine them periodically.

We should also monitor for scoliosis every time they visit for follow-up and look at posture/positioning in the chair/wheel-chair and give appropriate advice. It is also important to help with some exercises for the hands, in particular for the small muscles of the hands and to help them to continue writing at school for as long as possible. Now with the support system being offered for education for these children, many of them may be provided suggestions/advice regarding provision of extra time to write examinations, overlooking the poor hand writing and the use of scribes for the exams if necessary. Use of other aids like computers may be looked at although this may be equally as difficult for these children. One of the other common issues that these children face is abnormal weight gain as soon as they have marked difficulties with ambulation and so appropriate advice regarding the diet from a dietician would be important.

It is hoped that as the genes causing the various forms of HMSN are identified, more specific therapies may become available. Clinical trials using high dose vitamin C have not shown any clinical benefit in adults and children with HMSN type 1A, despite promising effects in transgenic mouse model.

GENETIC COUNSELING AND PRENATAL DIAGNOSIS

With the advent of molecular testing and the availability of the same commercially more and more children can be diagnosed precisely and the genetic mutations identified. This enables us to not only counsel the family about the chance of recurrence in the next pregnancy but also to perform prenatal diagnosis and even help prevent the recurrence of the same disease in the family.

Nowadays with the genetic tests and good neurophysiology facilities being available the need for nerve biopsy as a diagnostic tool is very limited.

IN A NUTSHELL

1. Hereditary motor and sensory neuropathy is a genetic disorder involving the motor and sensory nerves.
2. May be as a result of demyelination or axonal involvement.
3. The clinical varieties are similar mainly involving the legs and the hands.
4. There is marked genetic heterogeneity.
5. Age of onset varies with some starting in childhood and others in adult life.
6. Diagnosis is mainly by the clinical presentation, neurophysiology and genetic studies.
7. There is no definitive therapy as such.
8. Supportive care includes appropriate stretching exercises and splints.
9. Periodic follow-up of these children is needed to observe for scoliosis/trophic ulcers.
10. Genetic counseling and provision of prenatal diagnosis will help prevention of recurrence.

Chapter 43.11
Autonomic Neuropathies
Rachana Dubey, Ashok Jaryal, Sheffali Gulati

JN Langley first proposed the term autonomic nervous system (ANS) in 1921 and described its subdivisions as sympathetic, parasympathetic and enteric nervous system. ANS is ubiquitous and orchestrates important functions in many systems in the human body. The symptoms of ANS disorders are thus widespread and confounding due to multisystem involvement. Etiology of autonomic disorders is diverse; Familial dysautonomia was first described genetic autonomic disorder with many additions in primary category at present and ever expanding list of secondary involvement of ANS. Limited availability of diagnostic tests, lack of normative data in pediatric population and few treatment options are obstacles in managing pediatric autonomic disorders optimally.

THE ANATOMY AND PHYSIOLOGY OF THE AUTONOMIC NERVOUS SYSTEM

The ANS involves all major organs and consists of involuntary motor/effector system that is divided into sympathetic (thoracolumbar) and parasympathetic (craniosacral) divisions, each with a central and a peripheral component. In addition, there is an important enteric division. Outflow can occur independently or it is regulated and integrated by the central autonomic network (CAN). Embryonic development of the ANS is closely related to the development of the sensory nervous system; both have their embryonic origins in the multipotential neural crest cells. These cells migrate and develop into sensory and autonomic ganglia as well as the adrenal chromaffin cells.

Stimulation of *sympathetic system* leads to stimulation of many receptor systems resulting in dilation of the pupil, increase in glandular secretions, bronchodilation, increase in heart rate, decrease in gastrointestinal tract motility, and utilization of energy substrates. The *parasympathetic system* tends to have more local responses, but some effects may be multisystem, particularly with the wide-ranging innervation of the vagus nerve. **Table 1** suggests that they may not be exactly antagonistic contrary to popular belief.

Table 1 Effects of sympathetic and parasympathetic stimulation on various organs

Organ	Sympathetic nervous system	Parasympathetic nervous system
Heart	Increased rate Positive inotropism	Decreased rate Negative inotropism
Blood vessels (arterioles)	Constriction	None
Lungs	Bronchodilation	Bronchodilation
Gastrointestinal	Decreased motility	Increased motility
Kidney	Decreased output	None
Urinary bladder	Relax detrusor Contract sphincter	Contract detrusor Relax sphincter
Lacrimal glands	Slight secretion	Secretion
Salivary glands	Slight secretion	Secretion
Sweat glands	Secretion	Palmar sweating
Eyes		
Pupils	Dilatation	Constriction
Ciliary muscles	Relax (far vision)	Constrict (near vision)

SYMPTOMS OF AUTONOMIC DYSFUNCTION

Because the ANS and its CAN component have extensive effects that involve multiple systems, clinical manifestations can be extremely varied. When more than one system is affected, then a more global autonomic disorder should be considered on the basis of age at presentation. To understand these symptoms, a system wise approach is more helpful **(Table 2)**.

AUTONOMIC FUNCTION TESTS

There is growing need for objective quantitative autonomic function test centers for children and simultaneously to generate normative data in pediatric population. Laboratory testing has been developed to evaluate the functioning of cardiovagal, adrenergic and sudomotor aspects of the ANS **(Table 3)**.

Heart Rate Response to Deep Breathing (HRDB)

The HRDB provides an objective measure of the normal physiological response to breathing (sinus arrhythmia) **(Fig. 1)**. With a combination of verbal coaching and visual pacing, subjects are asked to breathe slowly and deeply at 5–6 times/minute. Heart rate during 8 cycles (inspiration and expiration each taking 5 seconds) is recorded and HRDB is calculated as the mean of the consecutive differences between maximal and minimal heart rate. Normative values exist for ages more than 9 years and HRDB is inversely related to age.

Heart Rate Variability

Heart rate variability (HRV) is measured by monitoring electrocardiogram for variable intervals (5 minutes to 24 hours) and analyzing R-R intervals. HRV can be reported as time domain or frequency parameters. HRV is an objective measure of the neural influences upon heart rate, which are due to naturally

Table 2 System-wise symptoms of autonomic nervous system dysregulation

System	Sign/dysfunction	Symptom
Cardiovascular system	Hypertension	Headache, visual symptoms
	Hypotension	Dizziness, light-headedness, blurring of vision, presyncope or syncope
	Arrhythmias	Palpitations, presyncope or syncope, acute life-threatening events
	Vasomotor changes	Mottling, peripheral cyanosis, blotching
Respiratory system	Alveolar hypoventilation	Apnea/cyanosis in sleep
	Apnea (insensitivity to hypoxia and hypercarbia)	Breath holding spells, acute life-threatening events, syncope
Sudomotor	Sweating disturbances	Hypohidrosis or hyperhidrosis, dry skin, clammy hands and feet, hyperthermia
Gastrointestinal	Oropharyngeal and esophageal dysmotility	Feeding difficulties, salivation, recurrent aspiration pneumonia
	Gastroesophageal reflux	Nausea, recurrent vomiting, aspiration pneumonia
	Colon dysmotility	Constipation, diarrhea, abdominal distension

Table 3 Autonomic function tests

Organ system	Autonomic component	Autonomic test
Cardiovascular system	Cardiovagal	1. Heart rate response to deep breathing (HRDB) 2. Heart rate response to standing (HRST) 3. Heart rate response to squatting (HRSQ) 4. Valsalva ratio (VR) 5. Heart rate variability (HRV)
	Adrenergic	1. Valsalva maneuver 2. Head-up tilt test (HUT) or tilt table test 3. Sympathetic skin response (SSR) 4. Biochemical (catecholamine levels)
Respiratory system	Control of breathing during awake and sleep states	Apnea monitoring Exogenous ventilator challenges Polysomnography Awake and asleep physiologic testing
Skin	Sudomotor	Quantitative sudomotor axon reflex test (QSART or QSWEAT) Thermoregulatory sweat test (TST)
Pupillary muscles	Sympathetic and parasympathetic	Pupillometry
Gastrointestinal system	Gastrointestinal motility	Gastric scintigraphy Colonic transit

opposing sympathetic and parasympathetic signals. HRV values should be interpreted according to physiological state. It can also be evaluated through visualization of scatter plots of successive R-R intervals known as Poincaré plots **(Figs 2A and B)**. Narrow scatter pattern will suggest decreased HRV and characteristic patterns are helpful in recognizing diseases like congenital central hypoventilation syndrome (CCHS) and rapid onset obesity with hypothalamic and autonomic dysfunction (AD).

Head-up Tilt or Tilt-table Test

Head-up tilt has been widely used for the evaluation of orthostatic tolerance. Lower extremities are restrained with the feet placed on a footboard so that no muscle is used to maintain the upright posture. In HUT, the patient is initially at rest supine for 10–30 minutes, then passively head end is elevated to 60–80°. In this state heart rate, blood pressure, and clinical status are monitored for 10–30 minutes. Patients might experience presyncope or syncope and test is aborted in this situation. Patients with orthostatic hypotension may **(Fig. 3)** or may not **(Fig. 4)** show compensatory increment in the heart rate in tilt position depending upon the functional state of baroreflex.

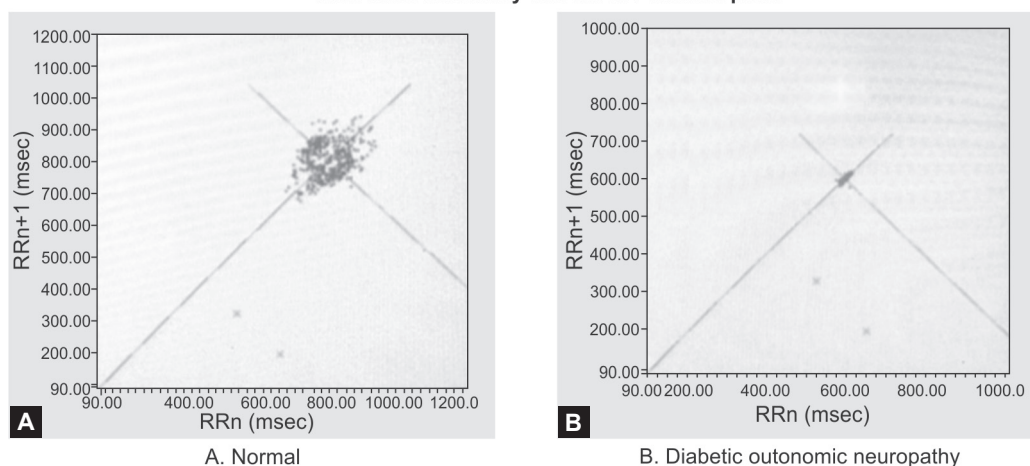
Sudomotor Testing (Quantitative Sudomotor Axon Reflex Test [QSART] or Quantitative Sweat Measurement System [QSWEAT])

These tests provide information about sweat glands and postganglionic sympathetic nerve fibers functions. QSWEAT is commercially available kit which is based on QSART. In QSWEAT, surface disks are placed through which a low-intensity current is passed to iontophorese acetylcholine through the skin and stimulate sudomotor sympathetic axons resulting in sweat production. The same capsule is used to provide acetylcholine for iontophoresis, guide the constant-current stimulus and collect data regarding the volume of local sweat formation. Sweat production is expressed in mL/cm^2 and compared to normative data.

Heart rate response to deep breathing (HRDB)
Figure 1 This record shows changes in the blood pressure and heart rate during deep breathing test or alternate deep inspiration and expiration. The blood pressure was measured noninvasively by Finometer®midi (Finapres Medical Systems, USA). The systolic pressure was computed from the pressure wave form while the beat-to-beat heart rate was derived from lead II of ECG

Heart rate variability in from of Poincare plots

A. Normal

B. Diabetic outonomic neuropathy


Figures 2A and B Poincare plots of healthy control. (A) Typical distribution of RRn and RR(n+1) in both axes. In loss of autonomic control of the heart, the distribution of the events is lost leading to centralization of the points; (B) The Poincare plot was made by HRVSoft (version 1.1, Autonomic Function Test Laboratory, AIIMS, New Delhi, India)

Head-up tilt (70°) in a patient of orthostatic hypotension without symptoms
Figure 3 This record shows changes in the systolic blood pressure and heart rate with passive head-up tilt (for 15 seconds) in a patient of orthostatic hypotension without symptoms. Note the progressive decrease in the blood pressure with concomitant increase in the heart rate. The blood pressure was measured noninvasively by Finometer®midi (Finapres Medical Systems, USA). The systolic pressure was computed from the pressure wave form while the beat-to-beat heart rate was derived from lead II of ECG

SYNCOPE IN CHILDREN AND ADOLESCENTS

Syncope is defined as the abrupt loss of consciousness and postural tone resulting from transient global cerebral hypoperfusion followed by spontaneous complete recovery. *Presyncope* is the feeling that one is about to pass out but remains conscious with a transient loss of postural tone. In the young patient, syncope may result from a fall in systolic pressure below 70 mm Hg or a mean arterial pressure of 30–40 mm Hg.

The syncopal event is typically preceded by a *prodrome* lasting from few seconds to 1–2 minutes with symptoms such as nausea, epigastric discomfort, blurred or tunnel vision, muffled hearing, dizziness, light-headedness, palpitations, pallor, cold and clammy skin, or weakness. These symptoms may occur variably in patients. Pediatric syncope is in general benign disorder but careful evaluation should be done to exclude a life-threatening cardiac or noncardiac disorder. There are many differential diagnoses to syncope in children and adolescents **(Box 1)**.

BOX 1 Differential diagnosis of syncope in children

- Neurocardiogenic syncope (vasodepressor or vasovagal)
- Orthostatic hypotension (OH)
- Postural orthostatic tachycardia syndrome (POTS)
- Cardiovascular mediated syncope
- Convulsive syncope
- Psychogenic syncope/panic attacks
- Situational syncope: Coughing, sneezing, micturition, defecation, deglutition (cold liquids), trumpet playing, suffocation, weight lifting, diving, etc.
- Drug and toxin induced
- Metabolic: Hypoglycemia, electrolyte imbalance, endocrine disorder.

Epidemiology

Syncope affects 15–25% of the children and adolescents. The incidence peaks around the ages of 15–19 years and there appears to be a female predominance. Before age 6, syncope is uncommon

Head-up tilt (70°) in a patient of orthostatic hypotension
Figure 4 This record shows a changes in the systolic blood pressure and heart rate with passive head-up tilt (over 15 seconds) in a patient of orthostatic hypotension who developed symptom (*) during the test leading to termination of test. Note the progressive decrease in the blood pressure without concomitant increase in the heart rate. The blood pressure was measured noninvasively by Finometer®midi (Finapres Medical Systems, USA). The systolic pressure was computed from the pressure wave form while the beat-to-beat heart rate was derived from lead II of ECG

and is seen in association with seizures, breath-holding spells, and cardiac arrhythmias. In children, neurocardiogenic syncope or vasovagal syncope or vasodepressor syncope is the most frequent cause of syncope (60–80%). The 5-year recurrence rate of syncope ranges from 33% to 50%.

Etiology

Detailed history of the event and physical examination will help in categorizing syncope into the three major types: (1) Neurocardiogenic syncope (neurally mediated/vasovagal/vasodepressor); (2) Cardiovascular-mediated syncope; and (3) Noncardiovascular syncope.

Neurocardiogenic Syncope

Previously known as vasodepressor, vasovagal, or neurally mediated syncope, is the most common cause of syncope. The history includes usual triggers such as postural changes, prolonged standing or sitting, obnoxious stimuli (anger, pain, sight of blood), and a positive family history.

Cardiovascular-mediated Syncope

In children, cardiovascular-mediated syncope is less frequent than in adults. It has a higher mortality and incidence of sudden death than neurally mediated syncope. A detailed cardiac history and important *red flags* **(Box 2)** suggest a need for an urgent pediatric cardiology referral. Many cardiac disorders can present as cardiovascular syncope in children **(Box 3)**.

BOX 2 Cardiac red flags in history of syncope

- History of heart murmur or congenital heart disease
- Acute attacks associated with hyperpnea or cyanosis
- Syncope during exercise or with exertion
- Family history of early sudden cardiac death, long QT syndrome, sensorineural hearing loss, familial heart disease
- Medications that can cause long QT syndrome, arrhythmias
- Absence of usual premonitory symptoms or precipitating factors associated with neutrally mediated syncope
- Unusual syncope triggers such as loud noises, fright, or extreme emotional stress.

BOX 3 Cardiovascular causes of syncope in children

- Arrhythmias
  - Complete heart block
  - Sick sinus syndrome
  - Tachyarrhythmias:
    - Supraventricular (Wolff-Parkinson-White-syndrome)
    - Ventricular
  - Ion channel abnormalities
    - Long QT syndrome (congenital or drug induced)
    - Brugada syndrome
- Cardiac: Structural
  - Aortic stenosis (valvular)
  - Hypertrophic obstructive cardiomyopathy
  - Coronary artery anomalies
  - Primary pulmonary hypertension
  - Eisenmenger syndrome
  - Mitral valve prolapse
  - Neuromuscular disorders
- Cardiac tumors.

Diagnostic Evaluation

A detailed history, a comprehensive clinical examination and an ECG have a combined diagnostic yield of 50% **(Box 4)**. The event history is most important in making diagnosis of syncope. Diagnostic evaluation should include an ECG on all patients with syncope, especially if it occurs with exercise and in younger children. All patients with risk factors for cardiac disease should be evaluated further by performing echocardiography, Holter or event monitor. Electroencephalography and neuroimaging are not recommended unless the loss of consciousness is not suggestive of syncope or seizure-associated syncope is suspected.

Management

The objective of treatment for neurocardiogenic syncope is to prevent recurrences; which leads to impaired quality of life, psychological distress, and substantial morbidity including school absenteeism. The mainstay of treatment of neurocardiogenic syncope is education and counseling of the patient, parents and teachers.

- Hematological and biochemical:
  – Complete blood count (CBC)
  – Serum iron, serum ferritin
- Cardiac evaluation:
  – Electrocardiogram (ECG)
  – Echocardiography
  – Holter or event monitor
- Autonomic evaluation:
  – Neurocardio autonomic reflex testing with and without tilt table testing
  – Quantitative sudomotor axon reflex test (QSART)
  – Thermoregulatory sweat test (TST)
- Miscellaneous:
  – Urine specific gravity and urinary sodium levels
  – Pregnancy test in menstruating adolescents.

Table 4 Primary and secondary disorders of pediatric autonomic nervous system dysregulation

Category		Disorders and Conditions
Primary	Developmental, genetic and syndromic	• Congenital central hypoventilation syndrome (CCHS) • Hereditary sensory and autonomic neuropathies II / III /IV • Alacrima, anhidrosis, adrenal insufficiency (AAAS)/Allgrove syndrome • Rett syndrome • Fragile X syndrome • Prader-Willi syndrome • Sodium channelopathies (*SCN9A* gene)
	Metabolic	• Mitochondrial disorders • Porphyria • Fabry disease • Menkes' disease • Dopamine β-hydroxylase deficiency and other neurotransmitter disorders (Norepinephrine transporter defect)
Secondary	Autoimmune	• Guillain-Barré syndrome • Paraneoplastic autoimmune polyneuropathy • Autoimmune neuropathy or ganglionopathy • Postural orthostatic tachycardia syndrome (POTS) • Lambert-Eaton syndrome or myasthenia gravis
	Paroxysmal disorders	• Recurrent syncope • Pheochromocytoma • Postural orthostatic tachycardia syndrome • Abdominal migraine and cyclic vomiting
	Disorders with associated autonomic dysregulation with known and unknown etiologies	• Diabetes mellitus and other endocrine disorders (thyroid disorder, Addison's disease, etc.) • Autism spectrum disorder • Migraine • Epilepsy • Illnesses causing small fiber neuropathies • Rapid onset obesity with hypothalamic dysfunction, hypoventilation and autonomic dysfunction (ROHHAD) • Drugs
	Infections	• HIV • Leprosy • Diphtheria • Chagas' disease • Botulism

Nonpharmacological Measures

The benign nature of these events should be explained and reassurance that these episodes would not result in epilepsy or sudden death. These will resolve within months to about 5 years after onset. Patients should be encouraged to maintain adequate hydration (1.5–2.5 L of water/day) and enhance dietary salt (2–5 g/day) intake. Patients should learn to recognize and avoid triggers. If the patients are on hypotensive medication, then they should be modified or discontinued. Isometric counterpressure maneuvers: leg crossing, buttock tensing and squatting may help in appropriate situations.

Drug Therapy

If despite conservative measures the syncopal episodes are recurrent, pharmacologic therapy may be tried. A wide variety of pharmacologic agents are given for prevention of neurocardiogenic syncope in children and adolescents.

- β-*adrenergic antagonists*: Propranolol (0.5–4 mg/kg/day), Atenolol (1–2 mg/kg/day)
- α-*adrenergic receptor agonist*: Midodrine (2.5–10 mg tid), pseudoephedrine (60 mg bid)
- *Mineralocorticoids*: Fludrocortisone (0.1–0.3 mg/day)
- *Others*: Anticholinergics, selective serotonin receptor reuptake inhibitors.

None of these agents, however has shown a consistent therapeutic benefit. Low-dose midodrine is currently recommended as first-line therapy for refractory neurocardiogenic syncope in children. Fludrocortisone should be used with increased salt intake for optimal effect.

AUTONOMIC DISORDERS

Table 4 lists the primary and secondary autonomic disorders.

HEREDITARY/PRIMARY AUTONOMIC DISORDERS

Hereditary Sensory and Autonomic Neuropathies

The hereditary sensory and autonomic neuropathies (HSANs) are due to genetic mutations that affect migration, differentiation, and survival of specific neurons, so that to some extent they can be considered neurocristopathies. With the exception of HSAN I, which is autosomal dominant disorder and starts in second decade, the other HSANs are present at birth and predominantly transmitted as autosomal-recessive disorders. In all HSAN patients, intradermal injection of histamine phosphate fails to elicit a normal axon flare response, which suggests reduced pain fibers as flare response depends on continuity of the peripheral axon and its cell body in the dorsal root ganglion. AD is associated with II, III, and IV subtypes of HSAN **(Table 5)**.

Hereditary Sensory and Autonomic Neuropathies-II

Classification of the HSANs is an ongoing process and has been aided by attempts to categorize the phenotype and identify the disease causing mutations; thus there are subtypes of HSAN I

Table 5 Classification of hereditary sensory and autonomic neuropathies

HSAN type	Chromosome/ Gene	Age at onset	Inheritance	Autonomic involvement
HSAN-I				
Type IA	9q22-q22.3/ SPTLC1	After second decade (all subtypes)	Autosomal dominant (all ubtypes)	Absent (all subtypes)
Type IB	3p24-p22/ Unknown			
Type IC	3q21/RAB7			
Type ID	Unknown/ Unknown			
HSAN-II				
Type IIA	12p13.33/HSN2 or WNK1	Birth-first decade	Autosomal Recessive	Present
Type IIB	5p15.1/ FAM134B	Childhood	Autosomal Recessive	Present
Type IIC	2q37.3/KIF1A	Childhood	Autosomal Recessive	Present
HSAN-III	9q31-33/ IKBKAP	Birth	Autosomal Recessive	Present
HSAN-IV	1q21-22/NTRK1	Birth	Autosomal Recessive	Present
HSAN-V	1p13.1/NGFB	Childhood	Autosomal Recessive	Absent

and II. Patients within the HSAN II classification exhibit profound sensory loss involving large and small fiber modalities. HSAN II is also known as Morvan's disease.

Clinical Features
Pain, temperature, and to a varying degree, position sense, are involved, and unrecognized injuries and fractures, as well as Charcot joints are seen frequently. Self-mutilation often begins with eruption of primary dentition and results in lip and tongue injuries. Deep tendon reflexes are depressed. Sensory nerve action potentials are absent. Taste sensation, corneal and gag reflexes are diminished. Hypotonia is common and may contribute to scoliosis. Cognition and motor functions are usually normal. AD varies from minimal to complex. Severe neonatal involvement is characterized by feeding problems and frequent apnea.

Management
Gastroesophageal reflux is common and sweating function is variable as hyperhidrosis as well as areas of anhidrosis can occur in the same patient. Blood pressure liability is not a feature of HSAN-II. Treatment is mainly symptomatic and preventative.

HSAN-III (Familial Dysautonomia, Riley Day Syndrome)
Familial dysautonomia was first genetic autonomic disorder to be recognized and is rarely seen outside Ashkenazi Jewish population. FD mutations lead to tissue-specific reductions in normal IKAP or hELP1 protein with subsequent downregulation of genes involved in neurogenic differentiation and migration of neural crest cells; finally affecting development of sensory and autonomic neurons. Unmyelinated and small myelinated neurons in the peripheral sensory nervous system and the ANS are reduced in number.

Clinical Features
- *Sensory symptoms* are less pronounced in FD compared to other HSANs. Corneal reflexes are depressed and gustatory sensation is diminished, because of absence of lingual fungiform papillae.
- *Motor symptoms* Absence of functional muscle spindles explains the loss of deep tendon reflexes and impaired sensorimotor control during walking, resulting in an ataxic gait. Motor milestones are commonly delayed, but cognition is usually normal.
- The *autonomic disturbances* are extensive. These patients have absence of tears (alacrima) with emotional crying and feeding difficulties due to poor oral coordination and hypotonia. Gastroesophageal reflux and frequent aspiration pneumonia eventually lead to chronic lung disease.
- *Dysautonomic crisis* can be triggered by emotional and physical stress; are associated with increased circulating catecholamines; present as prolonged periods of nausea and vomiting.
- *Vasomotor and cardiovascular* symptoms include erythematous skin blotching, hyperhidrosis, hypertension and tachycardia. It is now appreciated that FD is a disorder in which there is inability to modulate sympathetic activity and to release vasopressin by baroreflex-mediated stimuli. Therefore, patients exhibit profound and rapid hypotension without compensatory tachycardia with positional change.

Management and Prognosis
The mainstay of management remains preventative, symptomatic and supportive; includes measures to prevent dryness in eyes, fundoplication with gastrostomy to provide nutrition and avoid risk of aspirations, use of benzodiazepines and clonidine to control vomiting and the dysautonomic crisis, and fludrocortisone and midodrine to manage cardiovascular liability. Despite improved supportive measures only about 50% of the patients reach adulthood.

HSAN IV (Congenital Insensitivity to Pain with Anhidrosis [CIPA])
Hereditary sensory and autonomic neuropathies type IV is caused by mutations in the neurotrophic tyrosine kinase receptor type1 (*NTRK1*) gene. These are loss of function mutations, leading to impaired signal transduction at the nerve growth factor (NGF) receptor and poor survival of the nociceptive sensory and sympathetic neurons. Sural nerve biopsies show normal myelinated nerve fibers but unmyelinated fibers are absent. Skin biopsy shows deficient C and Aδ fibers in the epidermis and hypoplastic sweat glands without innervation.

Clinical Features
Anhidrosis causes episodic fevers and hyperthermia that is one of the earliest sign of the disorder. Anhidrosis also contributes to the thick skin, dystrophic nails, and reduced scalp hair. There are no cardiovascular symptoms in early childhood. Hyperactivity, severe learning problems are frequently present. Dysautonomic crisis and gastrointestinal dysmotility are not seen and emotional tearing is normal. However, the insensitivity to pain is significant leading to self-mutilation and autoamputation. There is poor healing of ectodermal structures, skin and bone.

Management
Prevention of hyperthermia and injuries are mainstay of management of HSAN-IV patients.

NEUROTRANSMITTER DISORDERS AND DOPAMINE-BETA-HYDROXYLASE DEFICIENCY
Dopamine-beta-hydroxylase (DbH) deficiency is an autosomal recessive disorder that affects catecholamine levels and control on autonomic functions. The enzyme DbH is required for conversion

of dopamine (DA) to norepinephrine (NE) so loss of DbH leads to reduced NE and accumulation of dihydroxyphenylalanine, DA, and its metabolites. As DbH is located predominantly in the adrenal medulla, clinical features of DbH deficiency are consistent with normal parasympathetic and sympathetic cholinergic function but reduced sympathetic noradrenergic function and adrenomedullary failure. This results in cardiovascular symptoms and orthostatic hypotension. In the perinatal period, DbH deficiency presents with vomiting, dehydration, hypotension, hypothermia, and hypoglycemia. By adolescent age, patients present with ptosis of the eyelids and profound orthostatic hypotension. The biochemical tests show minimal or undetectable plasma NE and epinephrine levels with a 5–10-fold elevation of plasma DA level. Treatment is symptomatic; L-threo-3, 4-dihydroxy phenyl serine (droxidopa, DOPS), which is converted peripherally directly into NE is used to improve orthostatic hypotension.

RESPIRATORY AND AUTONOMIC DISORDERS OF INFANCY, CHILDHOOD, AND ADULTHOOD

Most severely affected respiratory phenotypes within respiratory and autonomic disorders of infancy, childhood, and adulthood occur in CCHS and rapid-onset obesity, with hypothalamic dysfunction, hypoventilation, and autonomic dysregulation (ROHHAD). CCHS and ROHHAD are discussed here briefly.

Congenital Central Hypoventilation Syndrome

Congenital central hypoventilation syndrome (CCHS) is a rare, lifelong condition wherein control of breathing is abnormal and patients present with symptoms of alveolar hypoventilation. The severity of hypoventilation varies and most patients present in the neonatal period though late onset is also known. Central alveolar hypoventilation is diagnosed when the arterial PCO_2 is more than 45 mm Hg during wakefulness, due to decreased central ventilatory drive.

Congenital central hypoventilation syndrome is caused by a defect in the *PHOX2B homeobox* gene and inheritance is autosomal dominant. This gene maps to chromosome 4p12 and encodes for a transcription factor that plays a role in the regulation of neural crest cell migration and development of the ANS.

Diagnostic criteria The diagnosis of CCHS requires the following criteria as proposed by Keens and Hoppenbrouwers:
- Persistent evidence of hypoventilation during sleep [$PaCO_2$ > 60 mm Hg (8 kPa)]. Central alveolar hypoventilation
- Onset of symptoms usually in the first year of life
- Absence of primary pulmonary or neuromuscular disease or identifiable brainstem lesion
- No evidence of primary heart disease.

Clinical presentation Infants with CCHS typically present in the newborn period with episodes of cyanosis or apnea, and most require mechanical ventilation immediately after birth. Occasionally, infants may present in the first few months of life with acute life-threatening events. During sleep, infants will appear to have regular, shallow respiratory movements, with periods of central apnea. In some infants, hypoventilation may be seen during both wakefulness and sleep. Children with CCHS can also present with symptoms of end-organ damage from chronic, unrecognized hypoxemia and hypercarbia, such as cor pulmonale, seizures or developmental delay.

Other manifestations Diseases of neural crest origin, also known as neurocristopathies, are often associated with CCHS. These lesions result from aberrations in the migration, growth or differentiation of neural crest cells and include Hirschsprung's disease, which is

present in approximately 16% of cases of CCHS. Tumors of neural crest origin, including mediastinal or abdominal neuroblastoma or ganglioneuromas, may occur in 5% patients of CCHS. Other symptoms of AD seen in CCHS include temperature instability, excessive sweating, and swallowing dysfunction.

Diagnosis and management Congenital central hypoventilation syndrome has many differential diagnoses, neurological, respiratory, cardiac and metabolic diseases should be ruled out by relevant investigations. Genetic testing should be performed for the *PHOX2B* screening test which will identify the mutation in 95% of CCHS cases. The goal of treatment for CCHS is to ensure adequate oxygenation and ventilation during both wakefulness and sleep so as to avoid long-term neurological complications and *cor pulmonale* related to hypoventilation. Tracheostomy with positive pressure ventilation, noninvasive ventilation and diaphragmatic pacing has been tried in various combinations with reasonable success. Ventilators are adjusted to maintain CO_2 levels ideally between 30 mm Hg and 40 mm Hg and SpO_2 above 95%. Early individualized home ventilation and monitoring plan with periodic reviews is key strategy in patient management. Mortality in these patients remains high; the main causes of death include *cor pulmonale*, pneumonia and aspiration.

Rapid-onset Obesity, with Hypothalamic Dysfunction, Hypoventilation, and Autonomic Dysregulation

Children with ROHHAD typically present between the ages of 1.5 years and 9 years with rapid-onset obesity, followed by an evolving presentation that includes hypothalamic dysfunction, such as water imbalance, resulting in hyponatremia or hypernatremia, hyperprolactinemia and altered onset of puberty.

Criteria for preliminary diagnosis of ROHHAD include:
- Onset of alveolar hypoventilation after the age of 1.5 years
- Evidence of hypothalamic dysfunction, as defined by more than or equal to 1 of the following findings: rapid onset obesity, hyperprolactinemia, central hypothyroidism, disordered water balance, failed growth hormone stimulation test, corticotropin deficiency, or delayed or precocious puberty.

Nearly half of the children will experience a cardiorespiratory arrest. Typical presentation occurs after an intercurrent viral infection, then obstructive sleep apnea and hypoventilation are noted. Other symptoms of autonomic dysregulation include: low body temperature, cold hands and feet, severe bradycardia, and decreased pain perception. Approximately 40% of children with ROHHAD demonstrate a tumor of neural crest origin; which is often found in the adrenal gland but can also be found in the paraspinal area along the sympathetic chain. As there is no current genetic testing available for this disorder, the diagnosis of ROHHAD is based on the clinical presentation, the related clinical features, and the documented absence of other potentially confounding diagnoses, including ruling out late onset CCHS with *PHOX2B* testing.

SECONDARY CAUSES OF AUTONOMIC DYSFUNCTION

Guillain-Barré Syndrome

Autonomic dysfunction is a common and important complication in GBS and occurs in approximately two-thirds of patients and is often associated with a variety of derangements including cardiovascular, vasomotor, or dysfunctions in both the sympathetic and parasympathetic systems. Very rare pure autonomic variants of GBS, defined as pandysautonomia are also reported. One

pediatric study showed 50% prevalence of AD in mild childhood GBS and the prevalence of AD was much more common in the AIDP subtype than in the AMAN subtype. Up to 90% patients with moderate or severe GBS have AD. Sinus tachycardia is one of the most frequent manifestations and hypertension and postural hypotension are also common. HRV analysis is noninvasive and easily applicable, as it does not require any motor task. In GBS patients, reduced HRV has been reported.

HIV Infection
Neurologic complications of HIV are well-characterized in the central and peripheral nervous systems but not in the ANS, due to the complexities of measuring autonomic function in medically ill populations. AD is common in HIV, can be measured with an autonomic reflex screen, and is associated with distal symmetric polyneuropathy (DSP) but not with signs of CNS disease. Autonomic dysfunction was present in up to 90% of participants with severe DSP and in only 30% of participants with little or no DSP. Pathogenesis of DSP and autonomic involvement is not well-understood and can be seen despite treatment.

Diabetic Autonomic Neuropathy
Diabetic autonomic neuropathy (DAN) is among the least recognized complications of diabetes mellitus despite its significant negative impact on survival and quality of life in people with diabetes. DAN can involve the entire ANS. DAN may be either clinically overt or subclinical with one or more organ system dysfunction (e.g., cardiovascular, gastrointestinal, sudomotor, or pupillary). Clinically symptomatic autonomic neuropathy generally occurs many years after diabetes onset, though subclinical autonomic dysfunction can occur within a year of diagnosis in type II diabetes and within 2 years in patients with type I diabetes. Because of its association with adverse outcomes, including cardiovascular deaths, cardiovascular autonomic neuropathy (CAN) is the most clinically important and well-studied form of DAN. Reduced HRV seen in diabetic patients is suggestive of CAN. Gastrointestinal and pupillary dysfunctions are also common. Strict glycemic control is important for primary prevention. In future, gene therapy and pancreatic transplant will play important role in prevention of such complications.

IN A NUTSHELL
1. The ANS innervates every organ in the body, and autonomic disorders are pervasive and encompass a broad spectrum of symptoms.
2. The list of pediatric disorders with autonomic dysfunction, primary or secondary, is increasing every day and there is strong need to suspect and recognize them.
3. Cardiovascular system autonomic dysfunction is important cause of morbidity and mortality in many chronic illnesses.
4. Diagnostic facilities should be utilized for better understanding of pathophysiology and to plan out treatment.
5. It should be suspected in patients of diabetes mellitus, all disorders associated with sensory neuropathy and small fiber neuropathy.
6. Syncope in children is of neurocardiogenic type and is mostly benign.

Chapter 44.1

Principles of Endocrinology and Hormone Action

Khalid Hussain

The endocrine system consists of glands that synthesize and secrete hormones. A hormone is a specific chemical messenger molecule. These hormones are then carried in the blood stream to their target organ/s. Hormones allow communication between different organs and tissues. The hypothalamus, pituitary gland, thyroid gland, adrenal glands, parathyroid glands, the pancreas, ovaries, testes and the pineal gland constitute the main endocrine glands in the body **(Fig. 1)**. The gastrointestinal tract, heart, kidneys and adipose tissue can also produce hormones although these organs are not classical endocrine glands. Endocrine glands by secreting hormones regulate many physiological and biochemical aspects (such as growth, metabolism, reproduction, lactation, development and adaptation to stress) and help to maintain homeostasis.

PHYSIOLOGICAL AND BIOCHEMICAL ACTIONS OF HORMONE

A hormone is a chemical messenger that is synthesized and secreted by endocrine glands. It is then transported in the blood stream so that it can reach its target tissue/s where it will initiate its physiologic action. Hormones serve as a major form of communication between different organs and tissues. Hormones regulate many physiological and biochemical functions and help to maintain homeostasis. Although typically hormones are released into the blood stream and have their effect on a distant target organ, hormones may also have a paracrine action (affect the function of neighboring cells) or autocrine action (effects on the same cells that secreted the hormone).

Most hormones are synthesized as prohormones (proinsulin for example) which are then converted into the active form. In the circulation carrier proteins are able to bind to some hormones and help with their transport. However, only the free hormone (that fraction of the total hormone level which is unbound to any carrier protein) is active and available to bind to specific receptors to induce its effects.

Some hormone are water soluble (protein hormones like insulin) and are thus readily transported through the circulatory system whereas other hormones (steroid and thyroid hormones), are water insoluble and need to bind to plasma glycoproteins (e.g., thyroxine-binding globulin). Virtually all hormones have a pulsatile secretion pattern which is important for hormone action and tissue sensitivity.

The biochemical and physiologic effects of a hormone on its target tissue will depend on the concentration of the hormone in
Figure 1 Summary of the major endocrine glands in the body. The major endocrine glands include the hypothalamus, pituitary gland, thyroid gland, adrenal glands, parathyroid glands, the pancreas, ovaries, testes and the pineal gland

the circulation. Three factors (rate of production, rate of delivery and rate of degradation and elimination) regulate the levels of a hormone at the target tissue. Positive and negative feedback circuits (loops) play a role in regulating the synthesis and secretion of a hormone. Hormone elimination is characterized by the half-life of a hormone.

CATEGORIES OF HORMONES

Hormones can be chemically classified into three main categories—the hormones derived mostly from peptides and proteins; hormones derived from cholesterol and the amino acid derivatives.

Peptides and Proteins Hormones

Peptide hormones (such as thyrotropin-releasing hormone, TRH and vasopressin) are made of chains of amino acids. Protein hormones are made of longer chain of amino acids and examples include insulin and growth hormone (GH). Some protein hormones have carbohydrate side-chains (glycoproteins) attached and examples include follicle-stimulating hormone (FSH) and thyroid-stimulating hormone (TSH). Some protein hormones have to be synthesized as prohormones (e.g., proinsulin to insulin), which will only become active when they undergo proteolytic cleavage so that the active mature form of the hormone can be generated. The endoplasmic reticulum (ER) and the Golgi apparatus play important roles in synthesizing and transporting hormones so that they can be packaged into secretory vesicles for export.

Steroid Hormones

Cholesterol is important for the synthesis of steroid hormones. Testosterone and cortisol are examples of steroid-derived hormones. The first and rate-limiting step in the synthesis of all steroid hormones is conversion of cholesterol to pregnenolone. Once secreted, steroid hormones may be bound to albumin or by specific binding proteins. This binding to albumin or by specific binding proteins will alter the elimination and half-life of the hormone.

Amino Acid Derivatives

The amino acid tyrosine is a constituent of thyroid hormones and catecholamines. The amino acid tryptophan is used in the synthesis of serotonin and the pineal hormone melatonin. Thyroid hormones have a circulating half-life of the order of a few days and are inactivated by intracellular deiodinases. On the other hand, catecholamines are rapidly degraded, with circulating half-lives of only a few minutes.

FEEDBACK CONTROL OF HORMONE PRODUCTION

Negative feedback describes a feedback loop by which a hormone can regulate its own secretion. Negative feedback loops allow the maintenance of hormone levels within an appropriate physiological range. An example of a negative feedback loop is the regulation of thyroid hormone secretion **(Fig. 2)**.

Thyroxine and triiodothyronine (T4 and T3) are produced and secreted by the thyroid gland. The secretion of these two hormones is regulated by TSH which is released by specialized cells in the anterior pituitary gland called the thyrotropes. The function of the thyrotropes is in-turn controlled by cells located in the hypothalamus which secrete TRH. When the blood levels of T4 and T3 are above the physiological range they inhibit the secretion of TRH which in turn will reduce the secretion of TSH thus lowering the blood levels of T4 and T3.

HORMONE RECEPTORS

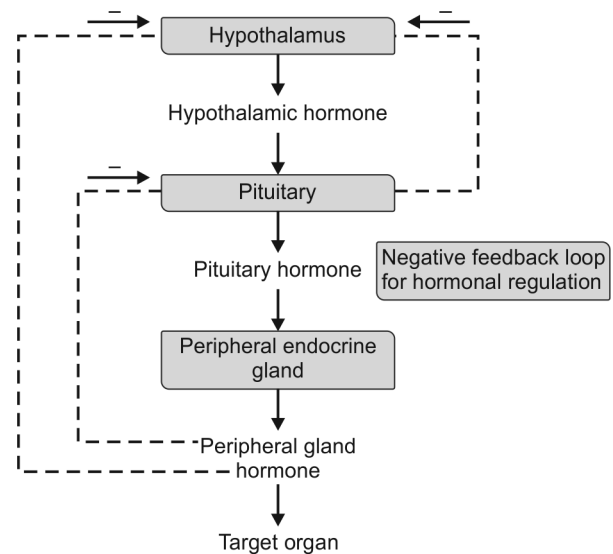
Hormone receptors are located either on the surface of the cell or within the cell, depending on the type of hormone. The binding of a hormone to its receptor triggers a cascade of reactions within the cell that regulates its function. Hormones can act as agonists where they bind their receptors and induce (augment) all the


Figure 2 An example of a negative feedback loop in hormonal control

post-receptor signaling events. For a given receptor, different agonists can have dramatically different potencies. Some hormones can act as antagonists where they bind the receptor and block binding of the agonist and prevent the triggering of the intracellular signaling events.

MECHANISMS OF ACTION OF HORMONES

There are two main classes of receptors, those located on the cell membrane (e.g., the insulin receptor) and those located in the cytoplasm (e.g., the glucocorticoid receptor). The receptors on the cell membrane can be classified into four main groups:

1. G-protein-coupled seven-transmembrane domain receptors [e.g., those for luteinizing hormone (LH), FSH, and TSH]
2. Single transmembrane domain growth factor receptors (insulin, insulin-like growth factor)
3. Cytokine receptors (cytokines, GH, prolactin)
4. Guanylyl cyclase-linked receptors (natriuretic peptides related to guanylyl cyclase second messenger system).

These receptors generally function via intracellular second messengers, including cyclic adenosine monophosphate (cAMP), cyclic guanosine monophosphate (cGMP), inositol 1,4,5-trisphosphate (IP3) and the calcium (Ca^{2+})-calmodulin system.

G-Protein-Coupled Receptor Signaling

G-protein-coupled receptors (GPCRs) are a large protein family of receptors that play important roles in signal transduction pathways. Hormone binding to GPCR induces a conformational change, thus allowing it to act as a guanine nucleotide exchange factor **(Fig. 3)**. The GPCR triggers activation of the associated G-protein by allowing the exchange of its bound guanosine diphosphate (GDP) for a guanosine triphosphate (GTP). The α subunit of the G-protein together with the bound GTP, can then dissociate from the β and γ subunits to further affect intracellular signaling proteins or target functional proteins directly depending on the α subunit type (Gαs, Gαi/o, Gαq/11, Gα12/13). The α-subunit possesses an intrinsic GTPase activity and hydrolyses GTP to GDP. This terminates the signaling cascade and α and $\beta\gamma$ reassociate.

Signaling via the Receptor Tyrosine Kinases

Hormones can also signal via receptor tyrosine kinases (RTK). RTKs are part of the larger family of protein tyrosine kinases, encompassing the RTK proteins which contain a
Figure 3 The G-protein-coupled receptors (yellow) triggers activation of the associated G-protein by allowing the exchange of its bound guanosine diphosphate for a guanosine triphosphate. The α subunit of the G-protein (red) together with the bound guanosine triphosphate, can then dissociate from the β and γ subunits (blue and green) to further affect intracellular signaling proteins or target functional proteins directly depending on the α subunit type (Gαs, Gαi/o, Gαq/11, Gα12/13). The α-subunit possesses an intrinsic GTPase activity and hydrolyses guanosine triphosphate to guanosine diphosphate

transmembrane domain, as well as the nonRTKs which do not possess transmembrane domains. When hormones bind to RTK, dimerization of the receptor occurs and this then stimulates the receptor's intrinsic protein-tyrosine kinase activity. This stimulates a signal-transduction cascade which brings about changes in gene expression and protein synthesis. Some RTKs are themselves protein kinases and become active (by phosphorylation) when the hormone binds. Insulin is an example of a hormone whose receptor is a tyrosine kinase.

Signaling via the Nuclear Receptors
Thyroid hormone and steroid hormone receptors are examples of receptors which are located inside the cell (cytoplasm or nucleus). They function as transcription factors by binding to a ligand. When the hormone binds to the receptor, it becomes competent to bind to DNA sequences **(Fig. 4)**. The hormone-receptor complex then attaches to the promoter regions of responsive genes and stimulates (sometimes inhibits) transcription from those genes.

Second Messengers
Second messengers are intracellular signaling molecules which when released initiate physiological changes such as proliferation, differentiation, migration, survival, and apoptosis. These second messengers function to amplify the initial signal. There are three major classes of second messengers: cyclic nucleotides (e.g., cAMP and cGMP), inositol trisphosphate (IP3) and diacylglycerol (DAG) and calcium ions (Ca^{2+}).

Cyclic AMP Second Messenger Systems
Cyclic adenosine monophosphate is a nucleotide generated when the enzyme adenylate cyclase acts on ATP. The cAMP concentration inside the cell can increase or decrease depending on the hormonal signal. When the cAMP concentration level increases it activates a cAMP-dependent protein kinase called protein kinase A. When protein kinase A is activated, it phosphorylates several other proteins which further trigger the signal cascade.

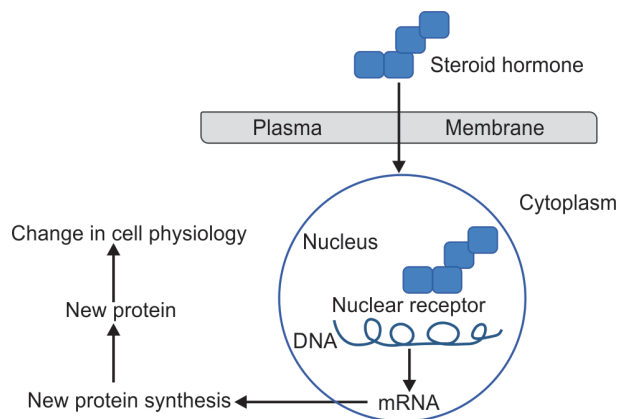
Inositol Trisphosphate and Diacylglycerol
Some hormones such as TSH and vasopressin function by binding to GPCRs that then activate the intracellular enzyme phospholipase C (PLC). PLC enzyme hydrolyses phospholipids, specifically phosphatidylinositol-4,5-bisphosphate (PIP2) which is found in the inner layer of the plasma membrane. Hydrolysis of PIP2 yields


Figure 4 An example of hormone signaling via nuclear receptors. The hormone-receptor complex binds to promoter regions of responsive genes and stimulates genes. The binding of the hormone to the receptor leads to a conformational change in the receptor and the receptor becomes competent to bind DNA. Activated receptors bind to hormone response elements, which are short specific sequences of DNA which are located in promoters of hormone-responsive genes. Transcription from those genes to which the receptor is bound is affected

two products, DAG and inositol-1,4,5-trisphosphate (IP3). DAG remains in the inner layer of the plasma membrane and recruits protein kinase C, a calcium-dependent kinase that phosphorylates many other proteins that bring about the changes in the cell. IP3 is a soluble molecule that diffuses through the cytoplasm and binds to receptors on the endoplasmic reticulum causing a rise in the intracellular calcium level.

Calcium Ions (Ca^{2+}) as Second Messengers
Calcium ions are important intracellular messengers and play key roles in numerous physiological processes. Calcium levels in the cytoplasm increase in response to numerous signals. The increase in the intracellular calcium level triggers a number of physiological processes including exocytosis (e.g., insulin secretion), release of neurotransmitters at synapses and muscle contraction. Calcium levels in the cytoplasm are normally maintained in the low (10–100 nM) range. In order to keep the calcium level low in the cytoplasm, calcium is actively pumped

from the cytoplasm to the extracellular space and into the ER, and sometimes in the mitochondria. Some proteins in the cytoplasm can act as buffers to bind Ca^{2+}.

OVERVIEW OF ENDOCRINE GLANDS AND THEIR FUNCTIONS

The endocrine glands in the body include the hypothalamus, pituitary gland, thyroid gland, adrenal glands, parathyroid gland, the pancreas, ovaries and testes and the pineal gland.

Hypothalamus

The hypothalamus is a part of the brain located superior and anterior to the brainstem and inferior to the thalamus. It plays a key role controlling the function of the various endocrine glands especially the pituitary gland. Specialized cells in the hypothalamus (neurosecretory cells) synthesize and secrete several key hormones. These include the growth hormone-releasing hormone (GHRH), growth hormone-inhibiting hormone (GHIH), corticotropin-releasing hormone (CRH), TRH and gonadotropin-releasing hormone (GnRH). The hypothalamus also is involved in synthesizing the hormones oxytocin and antidiuretic hormone (ADH).

These hormones which are released from the hypothalamus control the function of the anterior pituitary gland. For example GHRH will stimulate whereas GHIH will inhibit GH secretion.

With regard to the thyroid axis, the hormone TRH stimulates the anterior pituitary gland to secrete TSH. The secretion of FSH and LH is controlled by GnRH and adrenocorticotropic hormone (ACTH) secretion is regulated by CRH. The hypothalamus produces the hormones oxytocin and ADH; however these have to be transported to the posterior pituitary. In the posterior pituitary these hormones are stored and then released in response to stimuli.

Pituitary Gland

The pituitary gland (also known as the hypophysis) is situated in the small depression of the sphenoid bone called the sella turcica and is made up of two completely separate structures: the posterior and anterior pituitary glands. The anterior pituitary gland is the true glandular part of the pituitary gland. The function of the anterior pituitary gland is controlled by the releasing and inhibiting hormones of the hypothalamus (see above).

The anterior pituitary produces six important hormones: TSH is a tropic hormone responsible for the stimulation of the thyroid gland. ACTH stimulates the adrenal cortex to produce cortisol. FSH stimulates the follicle cells of the gonads to produce gametes—ova in females and sperm in males. LH stimulates the gonads to produce the sex hormones—estrogens in females and testosterone in males. Human GH affects many target cells throughout the body by stimulating their growth and regulating metabolism. Prolactin (PRL) stimulates the mammary glands of the breast to produce milk.

The posterior pituitary is actually an extension of the hypothalamus and contains axons of some of the neurosecretory cells. These neurosecretory cells secrete two hormones in the hypothalamus that are transported, stored and released by the posterior pituitary. Oxytocin triggers uterine contractions during childbirth and the release of milk during breastfeeding. ADH prevents water loss in the body by increasing the re-uptake of water in the kidneys and reducing blood flow to sweat glands.

Thyroid Gland

The thyroid gland is a butterfly-shaped gland located at the base of the neck and wrapped around the lateral sides of the trachea.

The thyroid gland synthesizes and secretes thyroid hormones as well as calcitonin. Thyroxine (T4) is the main hormone secreted by the thyroid gland. In the peripheral tissues T4 is converted to the biologically active triiodothyronine (T3). T4 and T3 have numerous physiological roles and play a particularly crucial role in brain maturation during fetal development.

Calcitonin (also known as thyrocalcitonin) is a 32-amino acid linear polypeptide hormone that is produced in humans by the parafollicular cells (also known as C-cells) of the thyroid gland. Calcitonin secretion is regulated by changes in the calcium level and if the serum calcium level rises above a certain point calcitonin will be released. Calcitonin lowers the serum calcium level by increasing the amount of calcium that gets into the bones.

Adrenal Glands

The adrenal glands are anatomically located above the two kidneys. They are made up of two layers—outer adrenal cortex and the inner adrenal medulla—with each one having different functions. The outer cortex mainly produces cortisol, aldosterone and androgens, while the inner medulla produces adrenaline and noradrenaline.

Glucocorticoids have many diverse functions, including the breakdown of proteins and lipids to produce glucose and function to reduce inflammation and immune response. Mineralocorticoids are a group of hormones that help to regulate the concentration of mineral ions in the body. Androgens, such as testosterone, are produced at low levels in the adrenal cortex to regulate the growth and activity of cells that are receptive to male hormones. The adrenal medulla produces the hormones adrenaline and noradrenaline under stimulation by the sympathetic division of the autonomic nervous system. Adrenaline and noradrenaline effects include increased heart rate and blood pressure, blood vessel constriction in the skin and gastrointestinal tract, blood vessel dilatation in skeletal muscles, bronchiole dilatation, and decreased metabolism, all of which are characteristic of the fight-or-flight response. Release of catecholamines is stimulated by nerve impulses, and receptors for catecholamines are widely distributed throughout the body.

The Pancreas

The pancreas is an endocrine gland producing several important hormones, including insulin, glucagon, somatostatin, and pancreatic polypeptide. The part of the pancreas with endocrine function is made up of clusters of pancreatic tissue called islets of Langerhans. Within the islet of Langerhans four main cell types exist namely β-(beta) cells which secrete insulin (decrease glucose in blood), α-(alpha) cells which secrete glucagon (increase glucose in blood), Δ-(delta) cells which secrete somatostatin (regulates/stops α and β cells) and PP-cells which secrete pancreatic polypeptide.

Gonads

The gonads—ovaries in females and testes in males—produce the sex hormones (testosterone and estrogen). Testosterone and estrogen play important roles in determining the secondary sex characteristics of males and females. In males the testes produce the male hormone, testosterone which is required for pubertal development. Testosterone also has many effects on other body systems including the muscles, bones, sex organs, and hair follicles. Testosterone causes growth and increases in strength of the bones and muscles, including the accelerated growth of long bones during adolescence. During puberty, testosterone controls the growth and development of the sex organs and body hair of males, including pubic, chest, and facial hair.

The ovaries are located in the pelvic body cavity lateral and superior to the uterus in females. The ovaries produce the female sex hormones progesterone and estrogens. Progesterone plays an important role during ovulation and pregnancy where it helps to support the development of the uterus and fetus. Estrogens regulate pubertal development (breast, uterine development, growth of pubic and axillary hair in the female). During adolescence estrogen plays an important role in controlling the growth of bones and thus regulating height.

The Parathyroid Glands

The parathyroid glands are small glands, usually four in number and are situated on the posterior aspect of the thyroid gland. The parathyroid glands synthesize and secrete parathyroid hormone (PTH), which regulates calcium ion homeostasis. When calcium levels drop below a certain level PTH is released from the parathyroid glands. PTH stimulates the osteoclasts to break down the calcium containing bone matrix to release free calcium ions into the bloodstream. PTH also triggers the kidneys to return calcium ions filtered out of the blood back to the bloodstream so that it is conserved.

The Pineal Gland

The pineal gland is located in the brain and produces the hormone melatonin. This is a serotonin derivative and plays an important role in determining sleep patterns.

Nonclassical Endocrine Glands

Several other nonendocrine organs produce hormones such as adipose tissue which produces leptin, the heart which produces the hormone atrial natriuretic peptide in response to high blood pressure levels and the placenta produces several hormones that help to maintain pregnancy.

IN A NUTSHELL

1. The hypothalamus, pituitary gland, thyroid gland, adrenal glands, parathyroid glands, the pancreas, ovaries, testes and the pineal gland constitute the main endocrine glands in the body.
2. Negative feedback describes a feedback loop by which a hormone can regulate its own secretion. It allows the maintenance of hormone levels within an appropriate physiological range.
3. Hormone receptors are either located on the cell membrane (e.g., the insulin receptor) or the cytoplasm (e.g., the glucocorticoid receptor).
4. Receptors on the cell membrane function via intracellular second messengers, including cAMP, cyclic GMP (cGMP), inositol 1,4,5-trisphosphate (IP3) and the calcium (Ca^{2+})-calmodulin system.
5. Cytoplasmic receptors function as transcription factors by binding to a ligand.

Chapter 44.2
Physiology of Neuroendocrinology

Priyanka Gupta, Vijayalakshmi Bhatia

The interactions taking place between the endocrine and the nervous system, both working together for control of homeostasis in humans, form the basis of neuroendocrinology. The main neuroendocrine glands are the hypothalamus, the pituitary and the pineal. In addition to maintenance of neuroendocrine-peripheral gland axes and endocrine rhythms, modulation of feeding behavior occurs via the neuroendocrine system.

NEURAL CONTROL OVER HORMONE SECRETION

Overall, the nervous system exerts its control over endocrine system in three ways:
1. *Direct autonomic innervation*, e.g., Sympathetic and para-sympathetic innervation of pancreatic islets of Langerhans and sympathetic innervation of adrenal medulla.
2. *Hypothalamic regulation of anterior pituitary* by specific releasing and inhibiting factors reaching via hypothalamic-hypophyseal portal circulation (discussed in detail below).
3. Hypothalamic regulation of posterior pituitary via hypothalamic-hypophyseal neural tract (discussed in detail below).

HYPOTHALAMIC-PITUITARY UNIT

Hypothalamus serves as the primary link between the nervous and endocrine systems by receiving the information regarding external environment (e.g., light, pain, temperature and smell) and internal environment [e.g., blood osmolarity, blood pressure (BP) and blood glucose levels]. With these inputs, hypothalamus exerts a control over both anterior and posterior pituitary as well as on the important brainstem cardiorespiratory, autonomic and limbic outputs. Circadian or diurnal rhythms characteristic of most pituitary hormones are taken care of by suprachiasmatic nucleus in anterior hypothalamus. Beside these roles, it also controls body temperature, thirst, appetite, energy, body fat composition, immunity, behavior, emotional expression, memory and visceral functions. Therefore, the disorders involving hypothalamus may involve a combination of these various functions.

Pituitary gland placed in sella turcica of sphenoid bone at the base of skull, has a glandular component (adenohypophysis) and a neural component (neurohypophysis). Adenohypophysis is subdivided into three distinct parts, i.e., *pars distalis* (anterior lobe), *pars intermedia* (intermediate lobe which is rudimentary in humans) and *pars tuberalis*. Adenohypophysis has five cell types (somatotropes, lactotropes, corticotropes, thyrotropes and gonadotropes) secreting six hormones **(Table 1)**. The neurohypophysis is composed of *pars nervosa* (posterior lobe), infundibular stalk and the median eminence. Due to its unique position in the brain, any increase in the size of pituitary (e.g., tumor) is associated with dizziness due to compression on brain above or vision problems due to compression on optic chiasma below or both.

The secretion of anterior pituitary hormones is controlled by hypothalamus through hypophysiotropic (releasing) and release inhibiting hormones **(Table 1)** released by a subset of parvicellular (small) neuronal cell bodies and also by the feedback from the circulating hormones of the target glands and paracrine and autocrine secretions of the pituitary itself. The posterior pituitary releases two hormones, i.e., ADH (antidiuretic hormone or vasopressin) and oxytocin, which are actually synthesized in the magnocellular (large) cell bodies of the supraoptic and paraventricular nuclei of the hypothalamus respectively. They are released from posterior pituitary in response to stimuli that are primarily detected in the hypothalamus.

MAINTENANCE OF NEUROENDOCRINE AXES

Each neuroendocrine axis maintains its activity at a set point by the integration of hypothalamic stimulation and peripheral hormonal negative feedback action on the pituitary and hypothalamus. The target organ hormone or its biochemical surrogate feeds back on the anterior pituitary and/or hypothalamus. Thus, if the peripheral hormone level falls, the secretion of hypothalamic-releasing hormone and pituitary tropic hormone will increase and vice versa in case of rise in peripheral hormone levels (*long loop feedback*). Anterior pituitary tropic hormones may also affect the synthesis or release their contemporary hypothalamic releasing or release-inhibiting hormone (*short loop feedback*). Hypophysiotropic hormones may inhibit their own synthesis and secretion also (*ultrashort loop feedback*).

ENDOCRINE RHYTHMS

Most endocrine rhythms are *circadian* (that is, synchronized with the day/night cycle). Over these circadian rhythms, *ultradian* secretory bursts (less than a day, i.e., minutes or hours) are superimposed. *Infradian* rhythms have cyclicity longer than 1 day, for example 28 day menstrual cycle. Growth hormone (GH) and prolactin (PRL) are secreted maximum after the onset of sleep. Plasma thyroid stimulating hormone (TSH) is maximum between 9 pm and 5 am and minimum between 4 pm and 7 pm. Levels of adrenocorticotropic hormone (ACTH) and cortisol start rising between 1 am and 4 am, peaking in early morning, falling during

Table 1 Hypothalamic and pituitary hormones

Hypothalamus	*Anterior pituitary hormones*
Anterior pituitary regulating hormones • TRH (thyrotropin-releasing hormone) • GnRH (gonadotropin-releasing hormone) • CRH (corticotropin-releasing hormone) • GHRH (growth hormone-releasing hormone) • Somatostatin (GHRIH, growth hormone release-inhibiting hormone) • Dopamine	• TSH (thyroid stimulating hormone, thyrotropin) • ACTH (adrenocorticotropic hormone, corticotropin) • GH (growth hormone, somatotropin) • FSH (follicle-stimulating hormone) • LH (luteinizing hormone, interstitial cell stimulating hormone) • PRL (prolactin, luteotropic hormone, lactogenic hormone, mammotropin)
Posterior pituitary hormones • ADH (antidiuretic hormone or arginine vasopressin, AVP) • Oxytocin	

the day time, and having a nadir at about midnight. PRL blood levels also peak in early morning hours. Gonadotropin secretion in adolescents is increased in the night.

It is important to understand these rhythms while taking into account the appropriate timing of collection of blood samples for assessment of hormone levels. Since these rhythms are mainly controlled by the hypothalamus, the loss of these rhythms may be the earliest sign of hypothalamic dysfunction.

CLASSIC HYPOTHAMIC-PITUITARY AXES

GHRH, GHRIH and GH

Growth hormone-releasing hormone (GHRH) stimulates secretion of GH and expression of *GH* gene in somatotropes of anterior pituitary. On the other hand, GH release-inhibiting hormone (GHRIH or somatostatin) inhibits secretion of GH and also that of PRL and TSH. Ghrelin, an appetite stimulant secreted from hypothalamus also increases GH secretion, thus coordinating nutrient acquisition with growth. Various physiological states and factors affecting GH secretion are listed in **Table 2**.

The major target organ of GH is liver where it stimulates formation of insulin-like growth factor-1 (IGF-1) forming a part of the hypothalamic-pituitary-hepatic axis. IGF-1 exerts a negative feedback effect on GH secretion both at pituitary and hypothalamic levels. In addition, GH itself exerts negative feedback on release of GHRH. GH also increases somatostatin release.

Dopamine and Prolactin

Among other cells of adenohypophysis, lactotropes are unique in the sense that the production and secretion of PRL is predominantly under inhibitory control of hypothalamus by dopaminergic tracts. Thus, the disruption of pituitary stalk and hypothalamic-hypophyseal portal vessels results in increase in PRL levels unlike a decrease in ACTH, TSH, GH, luteinizing hormone (LH) and follicle-stimulating hormone (FSH). Dopamine inhibits secretion of TSH and GH also.

As the name suggests the primary function of PRL is to favor lactogenesis, i.e., milk synthesis. It also influences development of mammary glands, reproductive functions and immune responses. Normal basal serum concentration of PRL is similar in men and women, which is increased during pregnancy, lactation and estrogen therapy. Sucking is the most important stimulus for prolactin secretion reflex. Stress, exercises, surgery, fear and stimuli causing arousal and some antihypertensive drugs and tricyclic antidepressants also increase PRL secretion. Thyrotropin-releasing hormone (TRH), angiotensin II, serotonin and opioids are other important PRL releasing factors. Dopamine agonist drugs

such as bromocriptine, somatostatin and gamma-aminobutyric acid (GABA) decrease PRL secretion. Negative feedback control over PRL secretion is mediated by PRL itself acting on the hypothalamus causing increase in dopamine synthesis and release (short loop feedback).

Corticotropin-Releasing Factor and Adrenocorticotropic Hormone

Corticotropin-releasing factor (CRH) causes a prompt release of ACTH and augments the expression of proopiomelanocortin (*POMC*) gene in corticotropes. POMC is cleaved to form β-lipotropin (which can be further cleaved into γ-lipotropin and β-endorphins) and ACTH (which can be further cleaved into α-melanocyte-stimulating hormone and CLIP, i.e., corticotropin-like intermediate peptide in lower vertebrates). CRH also stimulates sympathetic activity, increases BP and activates brainstem reticular activating system causing arousal, which complements the activity of hypothalamic-pituitary-adrenal (HPA) axis when exposed to stress.

Beside physical stresses like injury, infection, fever, surgery, anesthesia and hypoglycemia, psychological stresses like anxiety, fear and depression also stimulate ACTH secretion. ADH and interleukins (particularly IL-1, 2 and 6) also augment ACTH secretion.

Cortisol secreted from adrenal cortex in response to ACTH exerts negative feedback on the pituitary and the hypothalamus. Besides that, ACTH also negatively feeds back over CRH production. However, the hypothalamus has the ability to reset the set point of the HPA axis in response to stress which is obvious by the fact that response to many forms of stress can persist despite negative feedback from the high cortisol levels. Somatostatin, opioids, GABA and brain natriuretic peptide are other inhibitors of ACTH secretion and release.

Thyrotropin-Releasing Hormone and Thyroid Stimulating Hormone

Thyrotropin-releasing hormone from hypothalamus stimulates secretion and synthesis of TSH from thyrotropes of anterior pituitary. It also promotes the secretion and synthesis of PRL. Exposure to cold causes a sharp increase in TRH and TSH secretion. Secretion of TRH and TSH is suppressed by physical stress, starvation and infection. Temperature and the metabolic state also affect TRH secretion. The secretion of TRH and TSH is inhibited by triiodothyronine (T3) and thyroxine (T4) from thyroid gland by a negative feedback. Dopamine, somatostatin and GH also inhibit TSH secretion.

Table 2 Physical states/factors affecting growth hormone secretion

Stimulatory factors	Inhibitory factors
• Infancy and puberty	• Old age
• Slow wave sleep	• REM sleep
• Exercise	• Obesity
• Fasting	• Pregnancy
• Neurogenic and physical stresses	• Hyperglycemia
• Acute hypoglycemia	• Elevated plasma free fatty acids
• Hyperaminoacidemia (arginine, lysine)	• Elevated GH levels
• Hormones: estrogens, testosterone and acute rise in glucocorticoids	• Elevated IGF-1 levels
• Drugs: L-dopa, clonidine, apomorphine	• Chronic rise in glucocorticoids
• Neuropeptides: GHRH, ghrelin, galanin, opioids and melatonin	• Neuropeptides: somatostatin, calcitonin, neuropeptide-Y and CRH
• Neurotransmitters: acetylcholine, serotonin, histamine, GABA	

Abbreviations: REM, rapid eye movement; GHRH, growth hormone-releasing hormone; CRH, corticotropin-releasing hormone; GABA, gamma-aminobutyric acid.

GnRH, LH and FSH

Although, gonadotropin-releasing hormone (GnRH) primarily stimulates secretion of LH and FSH, it stimulates secretion of GH also. The pulsatile secretion and the frequency of pulses of GnRH have important effects on the gonadotropes. Continuous infusion of GnRH downregulates GnRH receptors, thus decreasing the FSH and LH secretion. At a frequency of 1 pulse/hour, GnRH preferentially increases LH secretion. At a slower frequency of 1 pulse/3 hours, GnRH preferentially increases FSH secretion.

Gonadotropin-releasing hormone secretion is influenced by various psychological, emotional and chemical factors. Norepinephrine stimulates; dopamine and endorphins inhibit GnRH secretion. Secretion of LH and FSH is under feedback control of estrogen, progesterone, testosterone, inhibin and activin secreted from gonads. In females, progesterone and testosterone negatively feeds back at the level of hypothalamus and pituitary. At low doses, estrogen also exerts negative feedback on FSH and LH secretion. However, high estrogen levels maintained for 3 days cause a surge in LH and to a lesser extent in FSH secretion. Thus, a positive feedback is observed at the hypothalamus and pituitary. In males, testosterone and estrogen negatively feeds back at the level of pituitary and the hypothalamus. Inhibin inhibits and activin stimulates FSH synthesis and secretion. PRL inhibits LH and FSH secretion by inhibiting GnRH secretion from hypothalamus, which may cause anovulation and amenorrhea in lactating mothers.

Antidiuretic Hormone

Antidiuretic hormone (ADH, also called arginine vasopressin AVP) increases water reabsorption in the distal convoluted tubules and collecting ducts of kidneys and regulates BP by contraction of smooth muscles of vessel walls. ADH increases ACTH secretion also both by its direct action on corticotropes as well as on the hypothalamus for the CRH release. This hormone also facilitates the memory by acting as a neurotransmitter in memory areas of brain.

Increase in plasma osmolarity more than 285 mOsm/L, decreased BP and decreased extracellular fluid (ECF) volume which is sensed by hypothalamus increases ADH secretion. Pain, nausea, vomiting, rise in intracranial pressure, stress, increase in temperature, standing, hypoglycemia and nicotine also increase ADH secretion. Decreased plasma osmolarity, increased ECF volume, decreased temperature, cortisol, thyroxine, atrial natriuretic peptide, ethanol and α-adrenergic agonists decrease ADH secretion.

Oxytocin

Two main physiological functions served by oxytocin in humans are the facilitation of labor and the ejection of milk. During labor, it is released in response to cervical stretch through a neuroendocrine reflex. The receptors for milk ejection reflex are located in and around nipples. Stressful stimuli facilitate oxytocin release. Its secretion is decreased by ethanol.

MODULATION OF FEEDING BEHAVIOR IN HUMANS

Various hormones, neuropeptides and neurotransmitters implicated in the regulation of appetite, satiety and energy expenditure in humans are listed in **Table 3**. They all interact together at the level of paraventricular hypothalamic nucleus (satiety neurons) and lateral hypothalamic nucleus (hunger neurons). Leptin (which is also called adipocytokine) is a cytokine derived from adipocytes signaling the hypothalamus about the degree of adiposity and nutrition. Neuropeptide-Y (NPY) is the principle neuropeptide and a very potent stimulator of food seeking behavior and inhibitor of energy expenditure. Many neurotransmitters and neurochemicals stimulate or inhibit the feeding by increasing or decreasing the release of NPY. **Flow chart 1** gives a simplified overview of how the body's adiposity status itself controls the food seeking behavior. The recently discovered hormone Ghrelin, secreted from the cells of oxyntic glands of stomach, appear to stimulate food intake by reacting with its receptors in hypothalamic neurons that express NPY. Serotonin produces satiety after ingestion of glucose. Gastrointestinal hormones like cholecystokinin and glucagon-like peptide-1 produce satiety by humoral effects, but their local production in brain may also participate in nutrient and calorie regulation.

PINEAL GLAND

Pineal gland, another neuroendocrine structure, is situated in the midline below the third ventricle. A number of functions are attributed to the pineal gland but none of them is decisively attributed to it in humans. Melatonin secreted by pineal gland is believed to be involved in the neurohumoral modulation of human sleep/wake cycle and many circadian rhythms. Although its role in human reproduction is not clear, many experiments show that the pineal gland exerts a negative effect on gonadotropic hormone secretion by pituitary, thus regulating the reproductive axis and the timing of onset of puberty. It is also proposed to slow or reverse the progression of aging. Exposure to continuous light decreases the activity of pineal gland and exposure to continuous darkness increases its activity. The most studied and established therapeutic utility of melatonin in humans is in the treatment of jet lag and circadian rhythm-based sleep disorders.

IN A NUTSHELL

1. Each endocrine axis has a three-tier configuration. The first tier is represented by hypothalamus, second tier by pituitary and the third tier by peripheral endocrine gland.
2. Anterior pituitary hormone secretion is under control of hypothalamus via various releasing and release-inhibiting hormones as well as the negative/positive feedback mechanisms.
3. Posterior pituitary hormones are synthesized in the hypothalamus and secreted from posterior pituitary in response to various external and internal stimuli detected at the level of hypothalamus.
4. Feeding behavior in humans is controlled at the level of hypothalamus by a complex interplay of various neuro-hormones, neuropeptides and neurotransmitters.
5. Pineal gland is an inseparable component of neuroendocrine system primarily concerned with the maintenance of circadian rhythms.

Chapter 44.3
Growth Hormone Deficiency and Resistance

Arpita K Vyas, Ram K Menon

During childhood, statural growth is one of the most important physiological processes. It defines the health and nutritional status of a child. Hence, it is vital for clinicians to demonstrate a good knowledge of assessing, interpreting and distinguishing normal from abnormal growth and investigate accordingly. Stature follows a Gaussian distribution and height within 2 standard deviations (SD) of the mean is considered normal height. An individual with a height below 2 SD is considered as having short stature.

A child's height should be measured and plotted on the normal standard (cross sectional or longitudinal) for that population as growth parameters vary by geographical location and ethnicity. Section 19 of this book provides a detailed discussion on growth charts and reference bases available in India, including those developed by Agarwal KN, et al. as well as the World Health Organization (WHO Multicentre Growth Reference Study) growth charts being used around the world, in particular in children below the age of 5 years.

It is important to recognize that deviation from normal growth could be the first manifestation of multiple disease processes both prenatal and postnatal in origin. This chapter focuses on growth hormone deficiency (GHD) and growth hormone resistance (GHR) as causes of poor growth. There is lack of consensus regarding the laboratory definition of GHD mainly because of the controversy surrounding the usefulness of growth hormone (GH) stimulation tests to diagnose GHD. Thus clinical features and auxologic measurements play a key role in the diagnosis of GHD/GHR.

PATHOPHYSIOLOGY OF GROWTH REGULATION

Role of Hypothalamus and Pituitary, and Transcription Factors in Growth

Endocrine regulation of growth is primarily controlled by the hypothalamic–pituitary axis. The arcuate nucleus of the hypothalamus synthesizes growth hormone-releasing hormone (GHRH) which stimulates the production of GH from the somatotrope cells in the anterior pituitary. The hypothalamic arcuate nucleus and periventricular nucleus also synthesize somatostatin which inhibits GH production. Pituitary is the *master gland* which remains central to regulation of growth. It also remains central to the regulation of other endocrine organs in the body including thyroid, adrenals and gonads. The gland is divided into anterior pituitary (adenohypophysis) which embryologically originates from the Rathke's pouch (diverticulum of the primitive oral cavity) and the posterior pituitary (neurohypophysis) originating from the neural ectoderm from the floor of the forebrain and unlike the anterior pituitary has no known function in growth.

The anterior pituitary (adenohypophysis) is functional by 12 weeks of gestation and is responsible for the production of GH **(Fig. 1)**. Multiple transcriptional factors are responsible for formation of the anterior pituitary gland and the determination of the cell lineage within the pituitary, and thus alterations in these transcriptional factors stage cause congenital GHD. The transcriptional factor responsible for the development of the anterior pituitary and optic nerve is the homeobox gene expressed in embryonic stem cells (*HESX1*) and inactivating mutation in
Figure 1 Development of the anterior pituitary gland and transcription factors involved in its differentiation

this gene results in septo-optic dysplasia (de Morsier syndrome), which is associated with deficiency of multiple pituitary hormones including GH. Other key transcription factors responsible for the development of the anterior pituitary include LHX3, LHX4, PTX2, and SOX3. PROphet of Pit1 (*PROP1*) is required for the initial determination of the pituitary cell lineage, including gonado-trophs. *Pit1* (also known as POU1F1) is responsible for differentiation of the cell lineage into thyroid-stimulating hormone (TSH), prolactin (PRL) and GH producing cells. Hence, inactivating mutation in the *PROP1* gene will not only lead to GHD but also lead to adrenocorticotropic hormone (ACTH), luteinizing hormone (LH), follicle-stimulating hormone (FSH), and TSH deficiencies, whereas inactivating mutation in *Pit1* will lead to TSH, PRL and GHD and spare the gonadotropes and corticotropes.

Growth Hormone Production, Secretion and Action (Fig. 2)

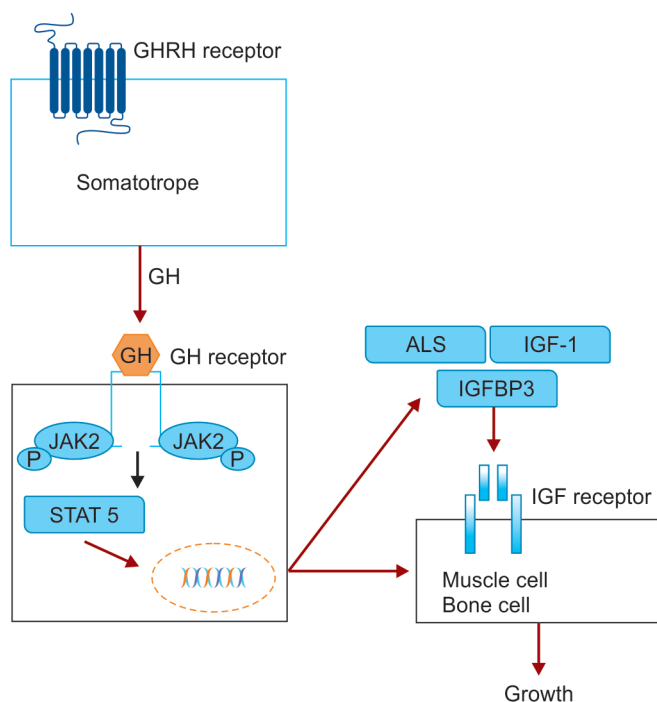
Growth hormone was isolated from human pituitary gland in 1956 by Li and Papkoff and the biochemical structure was defined in 1972. Human GH is a single chain 191 amino acid 22 kD protein and shares structural homology with PRL and placental lactogen and human GH variant. The gene coding for GH is present on chromosome 17. GH is secreted in a pulsatile manner and regulated by hypothalamic peptides including GHRH and somatostatin [somatotropin release inhibitory factor, (SRIF)]. The action of the GHRH receptor (G-protein receptor) on the somatotropes is dependent on the stimulation of adenylate cyclase. Somatostatin is secreted in response to the timing and amplitude of GH. Its binding to its receptor inhibits the adenylate cyclase activity and GH secretion. Neuropeptides (serotonin, histamine, norepinephrine, dopamine, acetylcholine, γ-aminobutyric acid, thyroid-releasing hormone, vasoactive intestinal neuropeptide-Y, vasopressin, corticotropin-releasing hormone and galanin) are also involved in the regulation and release of the hypothalamic factors, GHRH and somatostatin. The regulation of GH secretion by these neuropeptides forms the basis of various GH stimulation


Figure 2 Growth hormone secretion and action

tests employed in evaluation of GHD. GH secretion can also be affected by nonpeptide hormones like androgens, estrogen, thyroxine and glucocorticoid.

After secretion, GH binds to its receptor on the target organ. The gene for the GH receptor is present on chromosome 5. The receptor belongs to the class 1 cytokine receptor family and GH after binding to the receptor stimulates phosphorylation of downstream protein Janus kinase 2 (JAK2) and a cascade of phosphorylation (e.g., STAT 5b) and dephosphorylation events that ultimately results in increased transcription of target genes. Hence, a mutation in receptor gene or the various components of the downstream pathway can lead to GHR leading to poor growth.

Growth hormone also mediates the formation and secretion of insulin-like growth factor 1 (IGF-1) from the liver. IGF-1 is the principal mediator of the growth promoting effects of GH. IGF-1 circulates in blood bound to a family of binding proteins termed IGF binding proteins (IGFBP). There are six structurally related proteins in this group. IGFBP3 binds 75–90% of all IGF-1 present in circulation in a large heterotrimeric complex with a third protein, the acid labile subunit (ALS). ALS helps stabilize the complex and extends the half-life of IGF-1 in circulation. The remaining IGF-1 is bound to IGFBP1 whose concentration is controlled by nutritional status and IGFBP2 whose concentration is controlled by the amount of IGF-1 in circulation. IGF binds to the type 1 IGF receptor on target organs. The type 1 IGF receptor shares similarity with the insulin receptor but has higher affinity for IGF-1 and IGF-2 over insulin. On binding to its receptor IGF-1 activates tyrosine kinase with phosphorylation of downstream substrates and activation of discrete cellular pathways leading to specific biological actions.

GROWTH HORMONE DEFICIENCY

Epidemiology
Although data on incidence and prevalence of GHD are scarce, short stature due to GHD has been reported to occur in estimated 1/4,000–1/10,000 children depending on geographical distribution and the criteria used to diagnose the condition. Most cases of GHD are sporadic occurring as a result of developmental anomalies or

Table 1 Etiology of growth hormone deficiency

Congenital	*CNS malformations* • Holoprosencephaly/anencephaly • Pituitary aplasia/hypoplasia • Thin or absent pituitary stalk • Septo-optic dysplasia • Cleft lip and palate • Empty sella syndrome *Genetic mutations* • GHRH receptor mutation • Pituitary transcription factor mutations: *PTX2, LHX3, PROP1, POU1F1 (Pit-1)* • Growth hormone gene mutation
Acquired	*Trauma*: Head injury, birth trauma *Cranial irradiation*: > 30 Gy predispose to GHD *Brain neoplasm* *Infections/infiltration*: Meningitis, Langerhans histiocytosis, hemochromatosis

cerebral insult. In a small proportion (3–30% in certain studies) of cases, an affected first degree relative suggests a genetic etiology. It is generally accepted that incidence and prevalence of GHD is higher in boys compared to girls.

Etiology
Growth hormone deficiency can be divided into two broad categories: (1) congenital or (2) acquired deficiency **(Table 1)**. Congenital GHD may be subdivided into central nervous system (CNS) malformations, genetic and idiopathic.

Central Nervous System Malformations
These include midline craniocerebral or mid-facial abnormalities that lead to pituitary defects including pituitary hypoplasia, aplasia and complete absence of the gland. *Anencephaly* is associated with malformed, ectopic or hypoplastic pituitary gland. *Holoprosencephaly* is associated with hypothalamic defects that result in pituitary hormone deficiency. Cleft lip and palate, nasal septal aplasia and a single central incisor are associated with pituitary dysfunction including GHD.

Septo-optic dysplasia (SOD; de Morsier syndrome) This is a congenital malformation of the optic tract that comprises optic nerve hypoplasia and absent septum pellucidum. Approximately 50% of these children have hypopituitarism with the most common hormone deficiency being GH followed by TSH deficiency and ACTH deficiency. These patients are also at risk of developing diabetes insipidus. Patients with this condition have varying degree of visual field defects and diminished acuity and can also present with nystagmus. These patients can also have schizencephaly, absence/hypoplasia of corpus callosum and mental retardation. Mutations in the *HESX1* gene can manifest as SOD. However, in the majority of cases a definitive etiology is lacking. Fetal vascular accidents, young maternal age and maternal use of valproic acid are some of the predisposing factors of the condition. Approximately one-third of patients with optic nerve hypoplasia without involvement of the septum pellucidum are diagnosed with hypopituitarism.

Pituitary stalk interruption (aplasia/hypoplasia) This can occur during birth due to asphyxia with compromise to the vascular supply of the pituitary stalk. Both Diamond–Blackfan and Fanconi anemia are associated with interrupted pituitary stalk and GHD.

Empty sella syndrome This is diagnosed by MRI and is frequently associated with hypopituitarism and isolated GHD. Empty sella is composed of an enlarged pituitary fossa.

Genetic Etiologies

Syndromes These include Pallister–Hall syndrome (hypothalamic hamartomablastoma, micropenis, cryptorchidism), Rieger syndrome which is inherited in an autosomal dominant manner and is due to haploinsufficiency of *PITX2* gene (coloboma, dental hypoplasia, and prominent umbilicus), Prader–Willi syndrome (PWS) resulting from partial deletion of chromosome 15 or maternal uniparental disomy leads to GHD that is thought to be hypothalamic in origin.

Mutation in genes involved in GH production Mutations in the genes involved in development of the pituitary gland, GHRH receptor gene and growth hormone gene can lead to GHD.

1. Mutations in transcription factors responsible for pituitary formation and differentiation:

As described above the development of the pituitary gland is under the control of the coordinated expression of a cadre of transcriptional factors including HESX, LHX3/LHX4, SOX3, PITX2, and GLI2 that are responsible for the development of different pituitary hormone specific cell types. Mutations in these proteins are rare but can be the underlying etiology in patients with pituitary dysfunction where there is no other obvious etiology such as trauma or tumor.

Mutations (mainly homozygous) in *HESX1* gene located on chromosome 3p21.2 results in SOD and hypopituitarism inherited in an autosomal recessive manner.

PTX2 is an early development factor expressed in the rostral brain and is responsible for development of the pituitary gland and mutation in this gene primarily affects gonadotropes and to a lesser extent somatotropes and thyrotropes. This gene has been shown to be mutated in Rieger syndrome.

LHX3 is expressed in the anterior and intermediate lobes of the pituitary gland, the ventral hindbrain and spinal cord. The expression of this gene is responsible for differentiation of pituitary cells into somatotropes, lactotropes, thyrotropes and gonadotropes. Loss of function mutation leads to hypopituitarism with deficiency in GH, TSH, PRL, LH, and FSH. Other syndromic symptoms associated with these patients can include normal, hypoplastic, or enlarged anterior pituitary, a rigid spine with limited neck rotation, hearing loss, and ACTH deficiency.

PROP1 (prophet of Pit-1) is involved in the early determination and differentiation of multiple pituitary cell forms. Mutation in this gene is inherited autosomal recessively and results in deficiency of GH, prolactin, TSH, FSH, LH and occasionally ACTH. It is also a gene required for expression of POU1F1. Defects in POU1F1 (Pit-1) are associated with deficiency in prolactin, TSH and GH producing cells.

2. Mutation in the growth hormone gene (isolated growth hormone deficiency):

Type 1A This is characterized by large deletions in the *GH* gene leading to severe clinical phenotype including severe growth retardation in infancy and dwarfism. These patients frequently develop antibodies against exogenous GH due to lack of immune tolerance as a result of absence of GH in the intrauterine period. These patients eventually require IGF-1 therapy.

Type 1B This is a less severe autosomal recessive form of GHD.

Type II It is the most common form of isolated growth hormone deficiency (IGHD) and is inherited as an autosomal dominant condition.

Type III X-linked inherited form of partial IGHD in which the patients also have hypogammaglobulinemia.

3. GHRH receptor mutation:

Nonsense mutation in exon 3 of the GHRH receptor gene results in the *Dwarfism of Sindh*. The moniker *Dwarfism of Sindh* originates from cases of severe familial dwarfism reported from two villages in the Sindh province of Pakistan that have been proven to be due to mutation in this gene. This condition is inherited in an autosomal recessive manner and is commonly mislabeled as IGHD.

Acquired Forms of Growth Hormone Deficiency

Trauma Head trauma has been shown to damage pituitary stalk and infundibulum leading to anterior and posterior pituitary dysfunction including GHD. Birth trauma such as breech delivery, prolonged forceps delivery and prolonged labor all have been associated with hypopituitarism including GHD.

Central nervous system tumors CNS tumors in particular midline tumors such as germinomas, meningiomas, gliomas and colloid cyst of the third ventricle, and gliomas of the optic nerve are some of the causes of hypothalamic insufficiency. Local extension of craniopharyngioma and Hodgkin disease can also lead to hypothalamic dysfunction and thus GHD.

Infiltration and inflammation of brain and hypothalamus Langerhans cells histiocytosis or sarcoidosis can disrupt the pituitary stalk and lead to hypopituitarism and GHD. Viral and bacterial infections of the brain can result in hypothalamic/pituitary deficiency.

Irradiation of brain Cranial irradiation is associated with hypothalamic/pituitary dysfunction; the degree of pituitary involvement is dependent on the dose of radiation. Low dose irradiation leads to isolated GHD and higher doses lead to multiple pituitary hormone deficiency. A large proportion of children that receive irradiation to head of more than 30 Gy are GH deficient 5 years or more years out from therapy.

GROWTH HORMONE RESISTANCE

Failure to respond to exogenous or endogenous GH with appropriate growth rate and metabolic responses is defined as a GH resistant state. Conditions that result in GHR can be classified as genetic or acquired **(Fig. 3)**. The cardinal feature of all of the conditions described below is a clinical phenotype resembling GHD but the patient has *elevated circulating levels of GH*.

Genetic Etiologies

Conditions involving defects in GH receptor or postreceptor signaling can lead to elevated GH levels with poor growth. Conditions that lead to IGF-1 receptor defect or IGF-1 synthesis will also lead to GHR with poor growth and elevated GH. By definition GH treatment does not elicit a satisfactory response in these patients and treatment with IGF-1 may be the treatment of choice.

Growth Hormone Receptor Gene Mutation

Laron et al. were the first to describe clinical phenotype resembling GHD with high circulating GH level (Laron dwarfism), and this syndrome was subsequently attributed to mutations or deletions in parts of the GH receptor gene coding for the extracellular domain of the GH receptor gene. The human GH receptor gene is located on chromosome 5 and spans 86 kilobase pairs. Approximately 250 patients with Laron syndrome have been reported worldwide of which two-thirds are Arabs, Middle Eastern Jews and Oriental and Ecuadorian and the rest are Mediterranean or South Asian in origin.

Defects in Growth Hormone Receptor Signaling Pathways

STAT 5b mutations Growth hormone binds to its receptor, recruits and phosphorylates STAT 5b which in turn binds to and activates transcription of target genes that results in growth. Mutations

STAT 5b mutation
• Growth failure: severe
• GH: elevated
• GH binding protein: normal
• IGF-1: very low
• IGFBP3: very low

ALS mutation
• Growth failure: none/moderate
• GH: normal
• GH binding protein: normal
• IGF-1: very low
• IGFBP3: very low

***IGF-1 gene* mutation**

• GH: absent
• GH binding protein: normal
• IGF-1: very low
• IGFBP3: low

Liver disease
• Growth failure: mild/severe
• GH: normal
• GH binding protein: decreased
• IGF-1: normal
• IGFBP3: increased

Malnutrition
• Growth failure: none/mild
• GH: elevated
• GH binding protein: decreased
• IGF-1: varied
• IGFBP3: varies

Diabetes mellitus
• Growth failure: none/mild
• GH: elevated
• GH binding protein: decreased
• IGF-1: decreased
• IGFBP3: increased

Figure 3 Etiology of growth hormone resistance

(inherited autosomal recessively) in the gene coding for STAT 5b have been reported in approximately 10 patients. These patients apart from having identical phenotype to the GH mutation patients are also prone to immunodeficiency (T cell functional defects).

Conditions that Result in IGF-1 Deficiency due to Either Mutation in the IGF-1 Gene or IGF-1 Receptor Abnormalities or its Bioavailability

Mutation in the IGF-1 gene Mutation in this gene leads to failure of IGF-1 synthesis. These patients have low IGF-1, normal IGFBP3 and elevated GH levels but lack the craniofacial phenotype that is present in severe GHD and GH receptor deficiency.

Mutation in the IGF-1 receptor Homozygous mutation in this receptor is lethal. Heterozygous mutations have been described and lead to severe intrauterine growth retardation. These patients have normal/high IGF-1.

Mutation in the acid labile subunit gene (ALS) Acid labile unit is a protein that regulates the bioavailability of the IGF-1. ALS only binds to IGF-1 and IGFBP3 as part of the ternary complex and not to either one of these proteins individually. Patients with mutation in the *ALS* gene have an undetectable ALS and extremely low IGF-1 and IGFBP3, yet growth impairment is not as severe as that seen in GH deficient patients.

Acquired Growth Hormone Resistance

Growth hormone insensitivity can be caused by chronic illness like malnutrition (Kwashiorkor is characterized by elevated circulating levels of GH with low levels of IGF-1), liver disease

(IGF-1 biosynthesis is affected), poorly controlled diabetes mellitus (insulin deficiency results in decreased hepatic expression of the GH receptor and low IGF-1 production and a concomitant increase in IGFBP1 that inhibits IGF-1 action) and other catabolic states. Circulating antibodies to GH or its receptor can also cause growth failure.

DIFFERENTIAL DIAGNOSIS FOR PATIENTS WITH SHORT STATURE

While investigating a child with short stature suspected to be due to GHD, it is important to consider other etiologies for short stature and investigate for these accordingly.

Endocrinopathies

Hypothyroidism

One of the early and more prominent sign of acquired hypo-thyroidism is poor growth velocity and relative short stature. Hence, obtaining a TSH and free T4 is indicated in a child with poor growth velocity to exclude primary/secondary hypo-thyroidism.

Cushing Syndrome

Excessive glucocorticoids, whether exogenous or endogenous (excess ACTH or primary adrenal tumor), is a potent inhibitor of growth and negatively impacts growth velocity. GH secretion in these patients is typically normal and so is the circulating IGF-1 concentration.

Pseudohypoparathyroidism

These patients have dysmorphic features, poor growth velocity, obesity, and hypocalcemia and hyperphosphatemia due to parathyroid hormone (PTH) resistance.

Rickets

Both vitamin D deficient rickets and hypophosphatemic rickets lead to bony abnormalities like bowed leg resulting in short stature.

Chronic Diseases

Malnutrition

It is the most common cause of growth failure worldwide. In protein energy malnutrition, it has been shown that basal and/or stimulated circulating levels of GH are increased. In generalized malnutrition (marasmus) GH levels may be normal/low and IGF-1 levels are typically reduced.

Malabsorption

Poor growth can precede other clinical symptoms and signs of malabsorptive disorder. Celiac disease (gluten enteropathy) and Crohn disease should be considered in differential of poor growth. IGF-1 levels can be low in these conditions, hence it is important to rule these conditions out while investigating for GHD.

Renal Diseases

These include a variety of conditions that affect renal function and cause growth retardation (uremia, Fanconi syndrome and renal tubular acidosis are some examples). IGF-1 levels are usually normal, but there is increase in serum IGFBPs which could lead to inhibition of IGF-1 action.

Pulmonary Diseases

Cystic fibrosis leads to failure to thrive due to the primary pulmonary disease process and/or pancreatic disease. Chronic asthma in children requiring systemic steroids or high doses of inhaled steroids can lead to poor growth. In general, the decrease in growth velocity in these patients is reversible once the dose of inhaled/oral steroids is reduced; however, the extent of the catch-up growth is variable and generally less than satisfactory.

Chronic Infections

Chronic infestation with intestinal and systemic parasites (schistosomiasis, hookworm and roundworm), tuberculosis and HIV are some of the known causes of poor growth in Southeast Asia.

Hematological Diseases

Thalassemia leads to poor growth rate in children due to not only the chronic anemia but also due to iron overload induced endocrinopathies (hypothyroidism and gonadal failure) from chronic transfusions.

APPROACH TO DIAGNOSIS (FLOW CHART 1)

Growth Hormone Deficiency

Although there is debate about the exact criteria for the laboratory diagnosis of GHD, it is generally accepted that a combination of

Flow chart 1 Who to investigate for growth hormone deficiency?
Investigating a child with poor growth

History
- Birth history
- Past medical/surgical history
- Family history
- Nutrition history
- Social environment

Physical examination: General examination (dysmorphic features, birth marks, cardiac/pulmonary examination, abdominal examination, scoliosis, skeletal deformities)
Upper to lower body segment ratio
Growth chart: Assess growth velocity and percentile for height and weight

↓

Whom to investigate:
- Height below 2 SD of mean/mid-parental target
- Poor height velocity over 1 year

↓

Screening Investigations:
- Screen for chronic diseases:
  - Liver function test, kidney function test, hemoglobin
  - ESR, celiac screen, urinalysis
  - Bone age
- Karyotype (in girls)
- Thyroid function tests
- For growth hormone deficiency/resistance: IGF-1 and IGFBP3

Investigation suggestive of a chronic disease
Investigate accordingly for the disease concerned

Clinical and laboratory data suggestive of abnormal GH-IGF-1 axis
Peak GH level < 7–10 ng/mL on GH stimulation test with 2 different stimulants for GH secretion
- Consider brain MRI with pituitary protocol
- If brain MRI abnormal—treat underlying pathology first and then consider GH therapy
- If brain MRI normal—consider growth hormone therapy

clinical, radiological and auxological assessment together with biochemical investigations of the GH–IGF-1 axis should be used to diagnose the condition. In 2000, the Growth Hormone Research Society published consensus guidelines to assist in diagnosis of GHD.

Clinical Assessment for Growth Hormone Deficiency

Patients with following auxologic profile should be evaluated for GHD after excluding chronic illness/syndrome or other endocrinopathies:

- Severe short stature–height below 3 SD of mean for population
- Height below 2 SD of mean for population and height velocity that is more than 2 SD below the mean for 1 year
- Height 2 SD below midparental target height
- Height velocity more than 2 SD below the mean over 1 year or more than 1.5 SD over 2 years in the absence of short stature.

Evaluation consists of a detailed history including prenatal, postnatal environment and review of auxological data from birth. Family history of stature and age of onset of puberty should be reviewed. History of chronic disease/infection, nutritional status, cranial irradiation and psychological status should be reviewed. Parental heights should be obtained and midparental target height should be calculated.

Neonatal period Since fetal growth is largely GH-independent, newborns with GHD are of normal size. Hypoglycemia and prolonged jaundice with biliary sludging can be present in newborns with GHD, and hypoglycemia is more severe when GHD is present with ACTH deficiency. GHD in isolation or when combined with gonadotropin deficiency, in newborn, can present with micropenis and/or cryptorchidism.

Infancy and Childhood Infants with congenital GHD start to exhibit poor growth velocity by 6–12 months of age. Physiological catch-down growth in babies born larger than that predicted from mid-parental height, generally occurs in the first 2–3 years of life. Growth deceleration that occurs between 2 years and 3 years and the onset of puberty is likely to be pathological. A child exhibiting growth deceleration or whose height is 2 SD below the mean for that population warrants investigation for GHD only after excluding other causes of abnormal growth including endocrinopathies (hypothyroidism and Cushing syndrome), chronic diseases, syndromes (Turner syndrome/Prader–Willi syndrome) and skeletal dysplasia.

Children with GHD can have delayed eruption of dentition. GH is a lipolytic hormone and hence deficiency of GH results in increased body fat. However, a marked increase in BMI is not a feature of GHD. High pitched voice, delayed puberty, and micropenis are other features of GHD. Children with GHD exhibit delayed bone age with normal skeletal proportions. Muscle tone is usually low especially in infants leading to delay in development of gross motor skills. GHD results in poor growth of facial bones manifesting as small facies and underdeveloped nasal bridge. Hair growth is sparse in these patients.

Biochemical Assessment

As stated above a combination of clinical and auxologic together with biochemical data should be used to make the diagnosis of GHD. There is no one single biochemical test that is diagnostic of GHD. Since GH secretion from the pituitary gland is pulsatile, it is generally not useful to measure random levels of GH. Hence, if GHD is suspected, it is best to measure IGF-1 and IGFBP3 as a screening test prior to considering pharmacological stimuli to measure pituitary GH reserves. IGF-1 and IGFBP3 levels that are below 2 SD of reference range based on age and pubertal status suggest abnormality in the GH axis, but normal levels do not always exclude such a diagnosis. IGF-1 levels may be low in malnutrition and chronic liver disease. Pharmacological agents used to stimulate pituitary release of GH reserve include levodopa, clonidine, glucagon, propranolol, arginine and insulin. By themselves, each pharmacological stimulus has low specificity and hence administering sequentially two agents improves the specificity. GH peak level below 7–10 ng/mL is considered as being sub-normal. The precise threshold for categorizing a GH concentration as being low will depend on characteristics of the GH assay.

Radiological Assessment

In any child that presents with neurological signs/symptoms together with short stature or poor growth velocity, brain imaging and MRI with and without gadolinium with appropriate pituitary cuts is the imaging of choice. A child who fails GH provocative test and had the clinical features consistent with GHD warrants a brain MRI to exclude relevant pathology (abnormal pituitary gland/tumor). Bone age is helpful as it is usually delayed in patients with congenital GHD. It may not be delayed in those with acquired deficiency of short duration.

Growth Hormone Resistance

Clinical Assessment

One of the more prominent clinical finding is severe growth failure. Patients also have phenotypic features that resemble severe GHD including sparse hair, prominent forehead, high pitch voice, small face, small hands and feet, and delayed bone age amongst others.

Biochemical Assessment

Patients with GHR share many clinical features with GHD and hence should be screened with laboratory tests to exclude chronic disease. They also have low IGF-1 and IGFBP3 levels. GH binding protein (represents the extracellular domain of the GH receptor) is low in Laron syndrome patients with mutations in the extracellular domain. In patients with IGF-1 receptor defect, IGF-1 levels can be high.

Growth hormone levels are high when measured during GH provocative testing. These patients have increased levels of IGFBP1 and 2. Demonstration of mutation in the *GH* gene/IGF-1 receptor gene can help make a definitive diagnosis in some cases.

MANAGEMENT

Growth Hormone Deficiency

Once the diagnosis of GHD is made treatment with subcutaneously administered recombinant GH is instituted at a dose of 25–50 µg/kg/day with the aim of treatment being to maximize growth and final adult height with avoidance of side effects; within this framework, the dose will need to be adjusted on an individual basis. In patients with significant obesity, it is preferred to use 0.7–1 mg/m^2/day dosing rather than based on body weight. Patients with GHD exhibit a marked increase in growth velocity averaging 10–14 cm in the first year. This effect on growth velocity tends to wane over time.

Monitoring

Child on GH injections should be monitored every 3–4 months to assess how effective the drug is improving height velocity. Although side effects of GH are rare in children, they should be monitored with each visit. These include headaches (assessing for raised intracranial pressure), arthralgia, slipped capital femoral epiphysis, diabetes mellitus, and prepubertal gynecomastia. In epidemiological studies, higher circulating

concentrations of IGF-1 have been linked to certain malignancies in the normal population. Hence, there is a theoretical risk of increased risk of malignancy in patients treated with GH and the goal should be to keep IGF-1 level within normal range for age and pubertal status.

Poor growth in a child with GHD being treated with GH should prompt evaluation of thyroid hormone status since thyroxine deficiency can decrease the effectiveness of GH. Similarly, excessive doses of glucocorticoids in patients with ACTH deficiency as part of multiple pituitary hormone deficiency can dampen GH effectiveness. Hence every effort should be made to keep the glucocorticoid dose to the minimum required for physiological replacement and well-being.

Growth Hormone Resistance

Patients with GHR do not respond to GH. Recombinant IGF-1 was made available for subcutaneous use in 1990. The current recommended starting dose is 80 μg/dose twice daily. Maximal improvement in height is seen in patients with GHR/GH insensitivity within the first year and effect tends to wane in subsequent years.

Monitoring

A child on IGF-1 injection needs to be followed 3–4 monthly to follow growth velocity and monitor for side effects. One of the major side effects of recombinant IGF-1 is hypoglycemia that has been seen in about half the patients treated and is generally managed with food intake around the time of injection. Amongst other side effects that need to be monitored include benign intracranial hypertension, lymphoid hypertrophy (increased snoring and hypoacusis), and an increase in both lean and fat mass leading to increased BMI.

OUTCOME AND PROGNOSIS

We have come a long way since the isolation of pituitary GH in 1956. Prior to the availability of recombinant GH (in use since 1985), there was a concern of acquiring Creutzfeldt-Jakob disease with use of cadaveric GH which was also available only in limited supply. Since advent of recombinant GH, the quality of life of patients with GHD has improved significantly. Patients with IGHD or those associated with multiple pituitary hormone deficiency have a good prognosis for being healthy and maintaining a good quality of life.

Our knowledge regarding GHR is incomplete. Further progress in understanding the various mechanisms underlying this syndrome will help formulate novel treatments for this group of patients.

IN A NUTSHELL

1. Any patient with growth velocity below 2 SD of the mean of the population needs to be screened for GHD/GHR.
2. Accurate auxologic measurement assessment is crucial to making the diagnosis of GHD or GHR.
3. Random GH levels are not helpful in making biochemical diagnosis of GHD. Surrogate markers of GH action, IGF-1 and its primary binding protein IGFBP3, are useful screening tools for GHD.
4. In a child with poor growth being investigated for GHD, it is important to exclude other chronic diseases and endocrinopathies that cause poor growth.

Chapter 44.4
Polyuria, Diabetes Insipidus and Syndrome of Inappropriate Secretion of ADH

Tushar Godbole, PSN Menon

The posterior pituitary is an anatomical extension of the hypothalamus. It contains the axonal processes of the secretory neurons of the supraoptic and paraventricular nuclei of hypothalamus which produce, store and release the two hormones, arginine vasopressin (AVP, also known as antidiuretic hormone, ADH) and oxytocin.

PHYSIOLOGY OF WATER BALANCE

Regardless of large variations in water intake and evaporative water losses, serum osmolality is tightly maintained in a narrow range (280–295 mOsm/kg). This is accomplished by regulating the intake and output of free water. Intake requires the availability of water and an intact thirst mechanism. Excretion is controlled through the kidney via AVP.

Children have larger proportions of body water and have higher liquid intake during the early years of their lives. This poses challenges while treating disorders of water homeostasis in children. The control of plasma osmolality requires a complex integration of endocrine, paracrine, neural and behavioral systems. These include:

The sensors Various nuclei like the preoptic nucleus and organum vasculosum of the lamina terminalis, also called as osmoreceptors, are situated in the anterior hypothalamus and are capable of sensing changes in serum osmolality. They also receive minor inputs from various pressure and volume sensing organs. After stimulation, they send efferent signals to supraoptic and paraventricular nuclei to secrete AVP.

Regulation of water output **(Table 1)** Increase in the serum osmolality to the tune of even 1% above 283 mOsm/kg triggers the secretion of AVP. Once released, it stays in the circulation for 10 minutes. AVP acts on the V2 receptors of the cells of the collecting tubules in the kidneys. This causes expression of aquaporin 2 channels on the luminal membrane and causes absorption of free water; with parallel increase in urine osmolality. The concentration of AVP is directly proportional to the rise in serum osmolality. With maximum effect of AVP, urine osmolality can reach up to 900–1,200 mOsm/kg. Drop in blood volume is also a stimulus, though weaker than osmolality. Pain, stress, nausea and certain drugs also stimulate secretion of AVP **(Fig. 1)**.

Table 1 Common causes of polyuria in children and adolescents

Increased intake	Primary/psychogenic polydipsia (adolescents) Intraoperative fluid excess
Osmotic diuresis	Diabetes mellitus, mannitol
Failed renal reabsorption	Renal tubular acidosis Bartter and Gitelman syndromes Diabetes insipidus: central/nephrogenic
Increased solute excretion	Cerebral salt wasting Primary adrenal failure (mineralocorticoid deficiency) Mineralocorticoid resistance
Figure 1 The rise in plasma arginine vasopressin levels and exponential rise in urine osmolality in response to the rise in the plasma osmolality. Note that the threshold for thirst activation is much higher than threshold for AVP release.
Source: Robinson AG. Clinical Endocrinology and Metabolism. 1985; 14:55-88, with permission.

Regulation of intake-thirst mechanisms Rising serum osmolality and, to a lesser extent, hypovolemia trigger thirst. This mechanism, however, is activated after the initiation of AVP secretion. Hence, thirst is the savior when AVP fails to act, or is deficient. If thirst sensation is impaired, it makes the patient vulnerable to severe dehydration and hypernatremia.

Other systems contributing to water homeostasis Renin-angiotensin system responds to volume depletion and exerts the pressor effect on blood vessels. It also stimulates aldosterone production, which causes retention of sodium and thereby water retention. Angiotensin II gives inputs to hypothalamic nuclei. The natriuretic peptides (atrial, brain and C-type) act through inhibition of angiotensin II and aldosterone, thus causing natriuresis. These peptides are activated during conditions of volume overload.

APPROACH TO A CASE OF POLYURIA

In children polyuria is defined as urine output more than 4 mL/kg/hour or 2 L/m^2/day. Sometimes a urinary tract infection may appear to be polyuria due to the increased frequency of micturition. It is important to actually document the urine output to confirm polyuria before going ahead with the panel of biochemical and hormone testing. However, this is difficult in infants and toddlers, especially girls. In such cases, weighing the diapers helps. Associated polydipsia and disturbed night sleep due to thirst/urine frequency are reliable indicators of significant polyuria. The common causes of polyuria in children are listed in **Table 1**. History of central nervous system (CNS) insult such as head injury, meningitis or history of CNS symptoms such as headaches and visual disturbances needs to be asked in detail. Deficiency of other pituitary hormones needs to be looked for, such as short stature, central hypothyroidism, delayed puberty and easy fatigability with weight loss. Estimation of blood sugar, serum electrolytes, blood urea nitrogen (BUN), creatinine, urine

osmolality and specific gravity, urinary glucose, urine calcium and blood gases will rule out other causes of polyuria such as diabetes mellitus, hypercalciuria and renal tubular acidosis. Persistent polyuria in a diabetic child even after a good sugar control should raise suspicion of Wolfram (DIDMOAD) syndrome.

DIABETES INSIPIDUS

The term diabetes insipidus (DI) means passing large quantities of tasteless (dilute) urine. It reflects the inability of the kidneys to reabsorb the free water. It may result from deficiency of AVP secretion or its action **(Table 2)**. Nephrogenic DI is dealt with in detail in Section 41.

Clinical Features

A child with DI usually presaents with polyuria with preference to cold water as the main complaint. With intact thirst, the dehydration is compensated and the sodium as well as plasma osmolality are kept normal. Hypernatremia can be seen during infancy, during additional fluid losses such as diarrhea, or when the access to water is limited, e.g., post-CNS surgery. Midline defects and nystagmus are the clues toward septo-optic dysplasia. In cases of panhypopituitarism, the DI may get evident only after replacement of glucocorticoids. The presentation of DI during infancy is with growth failure, fever due to hypernatremic dehydration, and hydronephrosis.

Investigations

The osmolality of the serum is mainly contributed by sodium, urea and glucose. It can be calculated by the following formula:

Serum osmolality = 2[Na$^+$] + [Glucose/18] + [BUN/2.8] mOsm/kg

where Na is measured in mmol/L and both glucose and BUN in mg/dL. However, the correct and more reliable method is to actually measure the osmolality by an osmometer using the depression of freezing point method.

It is important to establish the diagnosis and then differentiate between central versus nephrogenic DI. Passing of hypo-osmolar urine [< 300 mOsm/kg] in the presence of hypernatremia or high serum osmolality (> 300 mOsm/kg) clinches the diagnosis of DI and one can proceed with testing for response to AVP. This is likely to be picked up when the urine and blood are collected soon after waking up before taking any fluids. But most of the patients have to drink frequently in the night, compensating for the dehydration and hypernatremia. In such cases, a formal water deprivation testing is required to induce hyperosmolality and make the diagnosis **(Flow chart 1)**.

Water Deprivation Testing
The following are the prerequisites before attempting this test:
- Child is not on any drugs for polyuria
- Normal or corrected cortisol and thyroid axis
- Child should be hospitalized and consent taken
- A good lab support to provide urgent osmolality readings.

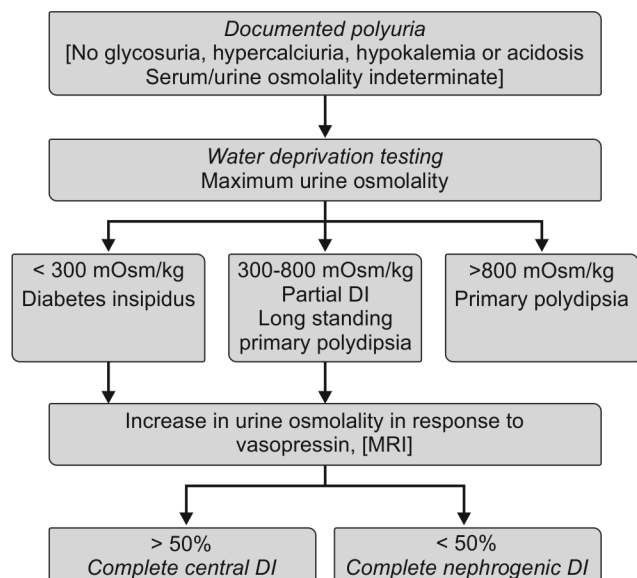
During the testing, the child is deprived of water to cause dehydration up to 5% of baseline weight or till serum osmolality goes above 300 mOsm/kg. This may take between 6 hours and 12 hours depending on the severity of polyuria. Serial recordings of weight, blood pressure and urine output are taken along with samples for urine and serum osmolality. If urine osmolality rises above 750–800 mOsm/kg, it rules out DI and suggests excess drinking. Inability to concentrate urine above 300 mOsm/kg when serum osmolality has reached 300 mOsm/kg and above, gives the diagnosis of DI. Urine values in-between suggest a partial DI or long standing primary polydipsia. Plasma AVP estimation is generally not required, but can be done in doubtful cases or in infants where formal testing is not possible. Measurement of the copeptin (C-terminal of the AVP prohormone) may serve as the surrogate marker of endogenous AVP secretion, but it is not yet validated.

The next step is to demonstrate the response to AVP while continuing with water deprivation. A serial rise above 50% in urine osmolality after a subcutaneous dose of AVP, 5 IU/m^2 confirms central DI, while a failed response suggests nephrogenic DI.

Imaging of the pituitary The normal posterior pituitary bright spot is usually absent in central DI, but it is not a specific sign. Thickening of the pituitary stalk may be seen with infiltrative or inflammatory conditions.

Table 2 Etiology and classification of diabetes insipidus

Central		
Congenital	*Panhypopituitarism*: Septo-optic dysplasia Holoprosencephaly Familial DIDMOAD syndrome (diabetes insipidus, diabetes mellitus, optic atrophy and deafness)	
Acquired	*Infection*: Tuberculous meningitis, others *Trauma*: Stock transection *Vascular insult*: Hypoxic injury, infarction, Sheehan's syndrome (postpartum) *Tumor*: Craniopharyngioma, optic glioma, germinoma, adenoma with apoplexy *Infiltration*: Histiocytosis X, autoimmune, sarcoidosis, leukemia	
Drugs	Phenytoin, halothane and alcohol	
Idiopathic	Up to 10–50% of cases	
Nephrogenic		
Congenital	X-linked, autosomal dominant, autosomal recessive	
Acquired	*Metabolic*: Hypocalcemia, hypokalemia *Renal disease*: Polycystic kidney, sickle nephropathy, obstructive uropathy, acute tubular necrosis, chronic pyelonephritis	
Drugs	Amphotericin B, demeclocycline, lithium, rifampin	

Flow chart 1 Approach to the differential diagnosis of diabetes insipidus


Management

Post-CNS Surgery/Trauma

Excess of intraoperative intravenous fluids is a common cause of polyuria during initial postoperative hours. Polyuria during first 24 hours of trauma or surgery may be transient DI and may revert spontaneously or develop into syndrome of inappropriate secretion of ADH (SIADH). In an unconscious patient, it is important to maintain balanced input and monitor serum sodium. In a conscious patient with intact thirst, ad-libitum water intake should be allowed. In case of massive polyuria, subcutaneous vasopressin may be given with a frequency just enough to control polyuria. Long acting desmopressin (DDAVP) is generally avoided, as the polyuria may be transient and DDVAP may cause hyponatremia.

Triple Response Following Head Injury

Following head injury or brain surgery, there is stunning of the neurons with surrounding edema leading to transient AVP deficiency and transient DI. As the edema subsides, beyond 2 days, there is release of AVP from the dying neurons giving rise to SIADH. After 10–14 days, permanent DI again reappears.

Permanent Diabetes Insipidus

After confirming the diagnosis, underlying cause if any, should be treated. DDAVP (a synthetic analog of AVP) has a half-life of 8–24 hours and is suitable for once or twice daily dosing. It is available as tablets and intranasal spray. Intranasal spray can be given at bedtime with dose between 2.5 µg and 10 µg. Commercial preparations deliver 10 µg as a spray, which may be a high dose for infants, hence a smaller dose can be sprayed intranasally using an insulin syringe. Oral tablets are also effective but the dosing is highly variable between 100 mg/day and 1,000 mg/day. It is advised to allow washoff of the drug (marked by reappearance of polyuria) before the next dose, in order to prevent hyponatremia. Free access to water during summer and illness is a must.

Nephrogenic Diabetes Insipidus

This clinical entity is discussed in detail in Section 41.

SYNDROME OF INAPPROPRIATE SECRETION OF ADH

Syndrome of inappropriate ADH secretion is also called as syndrome of inappropriate antidiuresis. This is caused by excess AVP secretion or inappropriate activation of its receptors in the kidneys. This causes fluid retention, dilutional hyponatremia, and low urine output with inappropriately high osmolality. Most of the volume excess is intravascular, hence there is no frank edema or anasarca. In chronic SIADH (beyond 48 hours), there is euvolemia due to compensatory mechanisms such as natriuresis and intracellular solute depletion.

The common causes of SIADH are given in **Table 3**.

Clinical Features

Worsening of neurological status in a setting of CNS injury may be due to SIADH-induced hyponatremia. Lethargy, confusion, altered sensorium are the symptoms of acute hyponatremia. Severe cases may develop seizures and unconsciousness. Chronic cases manifest with nausea, headaches, vomiting and muscle cramps. As opposed to other causes of hyponatremia such as cerebral salt wasting (CSW), in SIADH the child is not volume depleted. There are no features of dehydration, weak pulses or tachycardia.

Investigations

Serum osmolality is low (< 275 mOsm/kg). Serum uric acid is low in SIADH, reflecting the increased intravascular volume. Urine

Table 3 Etiology of syndrome of inappropriate secretion of ADH

Neurological/ Psychiatric	Trauma, post-CNS surgery *Infection*: Meningitis, encephalitis, abscess *Vascular*: Infarct, sinus thrombosis, bleeds Neoplasms Postictal phase of generalized seizure Guillain-Barré syndrome
Drugs	*Anticancer*: Vincristine, cyclophosphamide *Psychiatric drugs*: Amitriptyline, haloperidol Carbamazepine DDAVP overtreatment/misuse
Pulmonary	Pneumonia Lung abscess ARDS Positive pressure ventilation
Ectopic AVP	Carcinoma of lung, bronchus, pancreas, intestine and thymus Lymphoma, leukemia
Nephrogenic	Activating mutations of V2 receptors [Nephrogenic SIADH]
Miscellaneous	AIDS

Abbreviations: ARDS, acute respiratory distress syndrome; AVP, arginine vasopressin; SIADH, syndrome of inappropriate secretion of antidiuretic hormone.

osmolality is above 100 mOsm/kg (inappropriately high for hypo-osmolar plasma). The urinary sodium content is also marginally elevated (> 30 mEq/L) due to suppressed aldosterone and excess of atrial natriuretic peptide (ANP). A low urinary sodium (< 30 mEq/L) with elevated serum BUN suggests hypovolemia as the cause for hyponatremia, and rules out SIADH.

Management

Treatment is aimed toward restoring the sodium and water balance, and treating the underlying cause. Treating the underlying lung disorder or weaning from positive pressure ventilation promptly resolves the hyponatremia. Asymptomatic hyponatremia is corrected by limiting fluid intake, thereby causing loss of total body fluid. This can be achieved by giving fluids equal to insensible water loss plus the urine output. Hyponatremia should be corrected at a rate not more than 12 mEq in a day. Rapid correction may result in central pontine myelinolysis. Severe hyponatremia may be treated with furosemide-induced diuresis, which causes more water loss as compared to sodium. The urine output is then replaced with 3% saline. If the fluid restriction limits the food intake (as in infants), a situation similar to nephrogenic DI may be created with the help of demeclocycline. Newer V2 receptor antagonists like tolvaptan are being tried in adult patients with SIADH and hyponatremia. Vaptans prevent free water absorption from V2 receptor-mediated aquaporin channels.

CEREBRAL SALT WASTING

As the name suggests, this disorder is due to excess secretion of natriuretic peptides as a result of CNS injury, giving rise to natriuresis. The excess ANP suppresses AVP and aldosterone, causing polyuria and salt wasting. Clinical features include dehydration, hypovolemia and symptoms of hyponatremia. Lab tests reveal low serum sodium and elevated urinary sodium (> 150 mEq/L). Both SIADH and CSW have hyponatremia and increased urinary sodium, but the degree is severe in CSW with hypovolemia. Both DI and CSW have polyuria and dehydration but hyponatremia is seen only in CSW.

Cerebral salt wasting usually resolves spontaneously in 2–4 weeks after the CNS injury. Till that time, it is managed by

replacing the losses with isotonic (0.9%) saline and oral salt. Slow correction of serum sodium is recommended to prevent pontine myelinolysis.

PRIMARY POLYDIPSIA

It is the primary increased intake of water that gives rise to polyuria in these cases. The renal concentrating mechanisms are normal and the water deprivation testing usually yields increasing urine osmolality after deprivation. However, in severe long-standing cases, due to loss of medullary gradient, there may be partial concentration. It may be seen in psychiatric cases with compulsive water drinking (psychogenic), or in cases with altered thirst mechanisms (dipsogenic). The set-point of the thirst center can get altered after neurosurgical procedures like surgery for craniopharyngioma. Treatment involves restriction of water intake to physiologic levels. Drug therapy has no proven role.

Verbalis JG. Disorders of body water homeostasis. Best Pract Res Clin Endocrinol Metab. 2003;17:471-503.

IN A NUTSHELL

1. Water and sodium are controlled in a precise way, with complex interplay of various mechanisms.
2. Primary polydipsia, DI and CSW present with polyuria. While serum and urine sodium helps in differentiating between DI and CSW, differentiating between polydipsia and DI may require formal water deprivation testing.
3. Syndrome of inappropriate secretion of ADH and CSW both have hyponatremia with elevated urinary sodium, but CSW is accompanied by hypovolemia. SIADH needs fluid restriction, while CSW needs fluid and salt replacement.
4. Slow correction of the altered sodium levels is important for preventing CNS damage. Achieving euvolemia and eunatremia is the goal, but the underlying cause needs to be evaluated and corrected if possible.

Chapter 44.5
Thyroid Hormone Physiology
Anna Simon

The thyroid gland is the first endocrine gland to develop in the human body. This development and maturation can be considered in two phases; the first phase of embryogenesis of the thyroid gland and the second phase of maturation of the hypothalamic-pituitary-thyroid axis including hormone secretion and regulation. Thyroxine (T4) and triiodothyronine (T3), the two active hormones secreted from the thyroid gland, bring about their actions via a nuclear receptor, regulating the production of a variety of enzymes and proteins **(Table 1)**.

DEVELOPMENT OF THE THYROID GLAND

The thyroid gland originates as an outpouch from the floor of the primitive pharynx at the base of the tongue near the foramen cecum and descends through the tissues of the neck to the thyroid bed. The majority of the follicular cells are derived from this outpouching. This structure is further laterally fused with derivatives from the fourth branchial arches, the cells of which develop into the C cells or the parafollicular cells. As the thyroid gland descends, it remains connected to the foramen cecum by the thyroglossal duct which later becomes obliterated by the 7–10 gestational week. Failure of subsequent obliteration of the thyroglossal duct results in thyroglossal cyst formation.

A panel of transcription factors have now been identified, e.g., TTF1, NKX2.1, NKX2.5, PAX 8, FOXE1, HHEX are involved in organogenesis, development, differentiation and migration of thyroid gland.

Functional Maturation of the Thyroid Gland in the Fetus

Thyroglobulin synthesis has been documented as early as 4 weeks of gestation and iodide trapping by 8–10 weeks. The capacity to concentrate iodide and secrete thyroxine (T4) is acquired by 12 weeks of gestation. The maturation of the hypothalamic-pituitary-thyroid axis occurs in the second half of gestation, but complete maturation of the normal feedback mechanisms occur only during the second postnatal month.

Regulation of the Hypothalamic-Pituitary-Thyroid Axis

Thyroid stimulating hormone (thyrotropin, TSH) secreted from the pituitary thyrotropes binds to the TSH receptors (TSHR) and mediates several effects on thyroglobulin synthesis, thyroid hormone synthesis and release and also on thyroid cell growth. TSH secretion is regulated by thyrotropin-releasing hormone (TRH) production from the hypothalamus. Both triiodothyronine (T3) and T4 exert a negative feedback effect on TRH and TSH secretion.

Formation and Secretion of Thyroid Hormones

Thyroglobulin is synthesized by the thyroid follicular cells and is found in high concentrations in the colloid. Iodide is taken up at the basal membrane of the follicular cells by a sodium-iodide symporter and is transported to the cell-colloid interface where thyroid hormone synthesis takes place. The process is initiated by iodide transporter protein complex (which includes pendrin), thyroid peroxidase (TPO) and thyroid oxidases (DUOX1, DUOX2). The production of hydrogen peroxide by thyroid oxidase is the rate limiting step in thyroid hormone synthesis. TPO catalyzes the oxidation to iodine in the presence of peroxide and further catalyzes the iodination of tyrosine residues within the thyroglobulin molecule (organification) to form monoiodotyrosine and diiodotyrosine which couple together to form T3, T4 and reverse T3 (rT3) which are released into the blood stream. The released mono and diiodotyrosines are deiodinated and the iodine content is recycled for further use.

The thyroid secretes T4 (80%) and T3 (20%) and these hormones are carried in the blood stream bound to thyroid-binding globulin (TBG), transthyretin (TTR) and albumin. The actions of thyroid hormones are given in **Table 1**.

THYROID FUNCTION IN NEONATES

Thyroid Function in the Term Neonate

With exposure to cold and clamping of the umbilical cord, the serum TSH rises abruptly to 60–80 mU/L within 30–60 minutes of birth. This physiological surge of TSH then declines rapidly to about 20 mU/L at 24 hours and then gradually to about 6–10 mU/L at 1 week of age. Serum total and free T4 rises in parallel to the TSH surge and peaks at 24–36 hours. The hormonal levels then gradually fall in the first 4 weeks of life and stabilizes at slightly higher values than adults (Total T4 7–16 µg/dL, free T4 0.8–2 ng/dL, TSH 0.5–6 mU/L).

Table 1 Actions of thyroid hormones

CNS development and function	Increases myelin formation
	Stimulation of neuronal cell maturation and migration
	Stimulates dendritic branching and synaptic formation
	Influences other neurotransmitters, enzymes and cell proteins
Growth and development	Direct effects on growth
	Stimulates pituitary GH synthesis and secretion
	Stimulates insulin-like growth factor (IGF) synthesis and action
	Increases protein synthesis and facilitates muscle growth
	Enhances IGF-1 action on the bone/cartilage
Metabolic effects	Increases basal metabolic rate
	Thermogenesis
	Increases gluconeogenesis, glycogenolysis and stimulates insulin-mediated glucose uptake
	Increases lipolysis and fatty acid oxidation
	Stimulation of adrenergic receptor binding

Thyroid Function in the Preterm

Cord serum total T4 and free T4 varies with gestational age. The reference range for thyroid hormones, therefore, is dependent on gestation age and postnatal age. Preterm infants also undergo changes in serum TSH, T4 and T3 similar to term newborns but these changes are smaller because of immaturity of hypothalamic-pituitary-thyroid (HPT) axis. The decline in T4 levels after birth is more profound, resulting in *hypothyroxinemia of prematurity* most marked in infants born prior to 30 weeks gestation. Preterm infants also have very low levels of T3 due to immaturity of hepatic deiodinase. The immaturity of the HPT axis can also result in *delayed rise of TSH* in preterm hypothyroid baby, thereby affecting screening results.

Role of the Placenta

Placental transfer of T4 takes place throughout gestation, permitting relative protection of brain development in the hypothyroid infant, provided the mother is euthyroid. Though the placenta normally has limited permeability to T4, when there is fetal hypothyroidism and a significant gradient between the maternal and fetal circulation, there is an increased transfer of maternal T4 to the fetus. This transplacental transfer of maternal T4 has a critical role in limiting the negative consequences of hypothyroidism in the fetus. In contrast to T4, the placenta is freely permeable to iodide, antithyroid drugs, TSHR antibodies and some IgG immunoglobulins. Thyroglobulin and maternal TSH do not cross the placenta.

Thyroid Functions in the Critically Ill Neonate and Child

Euthyroid sick syndrome or nonthyroidal illness syndrome (NTIS) describes changes in thyroid hormone levels induced by critical nonthyroidal diseases. There are significant changes in the hypothalamic-pituitary-thyroid axis and the syndrome is characterized by low TSH, low T3 and low T4. NTIS has been considered as an adaptive phenomenon, but the cause and effect is still not clear and treatment with thyroxine may not be beneficial. It must also be remembered that drugs like glucocorticoids and dopamine which is often used in sick children can affect thyroid hormone assays.

IN A NUTSHELL

1. The thyroid secretes T4 (80%) and T3 (20%) and these hormones are carried in the blood stream bound to TBG, TTR and albumin.
2. Thyroid stimulating hormone secreted from the pituitary mediates several effects on thyroglobulin synthesis, thyroid hormone synthesis and release and also on thyroid cell growth.
3. Thyroid stimulating hormone secretion is regulated by TRH production from the hypothalamus.
4. Both triiodothyronine (T3) and T4 exert a negative feedback effect on TRH and TSH secretion.
5. At birth, the serum TSH rises abruptly to 60–80 mU/L within 30–60 minutes. This physiological surge of TSH then declines rapidly to about 20 mU/L at 24 hours and then gradually to about 6–10 mU/L at 1 week of age.

Chapter 44.6
Hypothyroidism and Thyroiditis
Palany Raghupathy

Hypothyroidism is the most common endocrine disorder in pediatric practice. Untreated congenital hypothyroidism (CH) in early infancy results in profound growth failure with irreversible developmental delay. Untreated hypothyroidism in older children also leads to growth failure, impaired memory and deceleration of metabolic functions. Prompt recognition of the hypothyroid state (by newborn screening in the case of a newborn and clinical evaluation in the older child), initiation of treatment, and continuous regular therapy as well as follow-up will ensure normal physical growth, and motor and intellectual development.

CONGENITAL HYPOTHYROIDISM

Congenital hypothyroidism is the most common and easily preventable cause of mental retardation in children. All efforts should, therefore, be made for timely identification of the affected newborn.

Epidemiology

The incidence of CH in the developed nations is nearly 1 in 2,000–4,000 live births, while studies in India have shown a higher incidence of approximately 1 in 1,200 live births. Newborn screening was established in Quebec, Canada in the 1970s, to diagnose CH early in the newborn period and to avoid the devastating outcome of severe mental retardation in children who were diagnosed late in infancy. Treatment for the affected infants commenced prior to 2 weeks of life and continued regularly will ensure normal physical and mental development **(Fig. 1)**. Newborn screening for CH is now universal in several countries of the world and is clearly warranted as it is a cost effective program for any nation or society.

Figure 1 A tale of two siblings. The younger one (left) with normal growth and development was detected to have congenital hypothyroidism by neonatal screening and was treated regularly. The older child (right) first presented at 2 years 6 months of age, and is not normal yet, physically and developmentally, despite regular treatment begun late

Pathogenesis and Pathophysiology

The causes of CH are listed in **Table 1**. Congenital malformations of the developing fetal thyroid gland or dysgenesis (including agenesis, hypoplasia or ectopia) form the majority of cases (85%). It occurs more frequently in females with a female: male ratio of 2:1. It may be associated with other congenital anomalies in a few cases (5%). Mutations in the *PAX8* gene and some mutations in the *TSHR* gene prevent or disrupt the normal development of the thyroid gland before birth and can cause agenesis or ectopia. Ectopic gland results from an impeded migration of the fetal thyroid from the pharynx to the neck **(Figs 2 to 4)**. The ectopic gland though functional, is incapable of adequate and sustained thyroxine production for life.

Dyshormonogenesis due to defects of iodide transport, peroxidase deficiency causing defective iodine oxidation and organification, or abnormal thyroglobulin (TG) synthesis, inherited by autosomal recessive mode, accounts for the remaining etiology of congenital primary hypothyroidism. Mutations in the *DUOX2, SLC5A5, TG, TPO*, and *TSHB* genes prevent or reduce the production of thyroid hormones, even though the thyroid gland is present.

The other less frequent causes of CH are: secondary or tertiary hypothyroidism, iodine deficiency, maternal thyroid antibodies suppressing neonatal thyroid function. A rare but serious cause is giant hemangioma, often seen in the liver. Increased consumption

Table 1 Causes of congenital hypothyroidism

Permanent	Transient
Dysgenesis	*Drug induced*

Large tongue	Clubfoot
Umbilical hernia	Subluxation of the hip
Wide fontanels	

Figure 5 Dyshormonogenetic goiter in the newborn

hypothyroidism in the infant. If the mother is also hypothyroid, the infant may have severe hypothyroidism at birth as the placental transfer of thyroxine is minimal in this situation.

Laboratory Tests

Thyroid hormone values in the newborn period are different from those in older age groups as shown in **Table 3**. Hence, thyroid function tests should be interpreted specifically for the age of the child and should include either serum free T4 or total T4 and TSH. It is also important to get thyroid function tests carried out only from reliable and accredited laboratories. T3 estimation is not useful as it may often be normal in CH. Low serum total or free T4

of free T4 occurs due to increased type 3′ deiodinase activity within the hemangioma, converting T4 to reverse T3 and T3–T2. T2 and reverse T3 are inactive thyroid hormones and hence the child develops clinical and biochemical features of primary hypothyroidism and requires thyroxine replacement often in very large doses, until the hemangioma shrinks spontaneously or with treatment. Periodic thyroid function testing is necessary in infants born with a large hemangioma.

Clinical Features

The clinical features of CH are enumerated in **Table 2**. When functional, an ectopic thyroid may escape detection on neonatal screening and may even support normal physical growth and development for a few years. Later, when it fails to deliver quantities of thyroxine commensurate for active growth, the child will present with an ectopically placed enlarged thyroid swelling in the lingual region or in the neck. In the neck, it is often confused for the thyroglossal cyst. Dyshormonogenesis is usually seen with a goiter or easily palpable thyroid gland in the newborn **(Fig. 5)**. When partly functional, it may support normal growth and development in childhood and may present with a goiter for the first time during rapid growth in adolescence.

Transient hypothyroidism caused by maternal factors is listed in **Table 1**. Iodine deficiency in the mother may lead to transient

Table 3 Age-related normal thyroid hormonal values

	TSH (ICMA)* mU/L	T4 (RIA)* μg/dL
Preterm (28–36 weeks of gestation)

Cord blood (≥ 37 weeks gestation)	2.3–13.2	5.9–15.0
Birth: 4 days**	1.0–38.9	14.0–28.4
2–20 weeks	1.7–9.1	8.1–15.7
21 weeks to 20 years	0.7–6.4	5.6–14.9

* ICMA, immunochemiluminescence assay; RIA, radioimmunoassay.
** Newborn physiological TSH surge occurs half an hour after birth and lasts about 2–4 days

concentrations with markedly elevated serum TSH level are seen in nearly all cases of CH except central hypothyroidism, wherein low serum total or free T4 are seen along with low serum or normal TSH as well. This will need to be distinguished from thyroxine binding globulin (TBG) deficiency.

Radiograph of both knees will show absence of (or small size) of the lower femoral and/or upper tibial epiphyses.

Thyroid nuclear imaging is useful to decipher the etiology of CH and helps in convincing the parents regarding the permanent nature of the condition and the need for lifelong therapy. Nuclear scan must be planned prior to or within a week after commencement of thyroxine to avoid blocking of the radionuclide tracer uptake by the thyroid. ^{99m}Tc scan provides anatomical details of the thyroid. ^{123}I scan with perchlorate discharge test will help to delineate dyshormonogenetic defect of iodide organification.

When nuclear scan is not available readily, therapy with thyroxine should never be delayed. Determination of the etiology in such cases or in doubtful cases may be carried out after the third birthday, after stopping thyroxine safely for 4–6 weeks.

Thyroid ultrasonography is useful to delineate the presence of the thyroid when it is not demonstrated on nuclear scan because of poor tracer uptake caused by maternal thyroid antibodies, or antithyroid drug therapy.

Treatment

Treatment for CH is replacement of the deficient thyroxine in the form of levothyroxine tablet, at a dose of 10–15 μg/kg/day (for newborns), once daily. The tablet is crushed and mixed with a small quantity of water or expressed breast milk and administered with a spoon or dropper ensuring all the particles are given entirely, preferably on an empty stomach. Thyroxine is unstable in suspension form. The parents have to be educated appropriately regarding regular therapy, and the need for its lifelong duration. Dosage adjustment will be required during follow-up with increasing age repeat thyroid function testing is done a month after commencing therapy and subsequently once in 3–6 months. Monitoring of the child's growth and development at regular intervals is essential.

Ectopic thyroid should never be removed, as this may be the only thyroid tissue in the child. Medical therapy with thyroxine replacement will effectively reduce the size of the swollen ectopic thyroid. Even transient hypothyroidism may be potentially harmful to the infant and hence thyroxine therapy should be given temporarily until one is convinced that the infant is able to produce normal amounts of thyroxine required or until resolution of the underlying cause.

If thyroxine therapy had been commenced on purely suspicious grounds without confirming a permanent cause or without adequate etiological work-up initially, thyroxine may be stopped for 4–6 weeks after the age of 3 years to establish the permanent nature of hypothyroidism and thyroid function tests repeated.

Prognosis

Early initiation of thyroxine therapy for permanent hypothyroidism will lead to acquisition of normal academic skills and these children will compare well with their unaffected peers.

HYPOTHYROIDISM BEYOND THE NEONATAL PERIOD

Childhood hypothyroidism with onset after 6 months of age is also known as *acquired hypothyroidism* and may be primary (at the level of thyroid gland), secondary (at pituitary level) or tertiary (at level of hypothalamus).

Epidemiology

Acquired hypothyroidism is sporadic in a large majority of cases. Around 15% of cases are due to inherited biosynthetic defects of thyroxine **(Box 1)**.

Chronic lymphocytic thyroiditis (CLT) or Hashimoto thyroiditis is the most frequent cause of acquired hypothyroidism in 1–2% of adolescents in early to midpuberty, but may also occur in younger children and in either sex with female sex predominating (F : M ratio 2 : 1) in all age groups. This is an autoimmune disease with inherited predisposition and may also be initiated by environmental factors. Activation of CD4 (helper) T-lymphocytes specific for thyroid antigens initiates the autoimmune process. The net result is hypothyroidism due to destruction of the thyroid by lymphocytes and cytokines. However, thyroid stimulation by antibodies may also lead to Graves' disease. Antithyroglobulin and antimicrosomal (antithyroid peroxidase, TPO) antibodies are present in nearly 90% of cases, the latter being more sensitive and specific. Thyroid antibodies serve as useful markers of CLT and are not believed to play a role in the pathogenesis of CLT. Family history of either CLT or Graves' disease is encountered in nearly one-third of cases.

Chronic lymphocytic thyroiditis may present by itself or along with other autoimmune conditions **(Box 2)**, e.g., in 20% of children

---

BOX 1 Causes of acquired hypothyroidism in children

Primary hypothyroidism
- Chronic lymphocytic (Hashimoto) thyroiditis
- Chromosomal and other disorders associated with autoimmune thyroiditis **(Box 2)**
- Late onset CH
  – Thyroid dysgenesis
  – Thyroid dyshormonogenesis (inborn errors of thyroid metabolism)
- Drugs
  – Anticonvulsants
  – Amiodarone
  – Lithium
  – Antithyroid drugs
- Infection
- Infiltration
- Iodine deficiency

Secondary/tertiary hypothyroidism
- Craniopharyngioma
- Tumors compressing hypothalamus/pituitary
- Neurosurgery
- Cranial irradiation
- Head trauma

Thyroid hormone resistance.

BOX 2 Conditions associated with autoimmune thyroid disease

- Down syndrome
- Turner syndrome
- Noonan syndrome
- Klinefelter syndrome
- Addison disease
- Celiac disease
- Polyglandular autoimmune disorder
- Vitiligo
- Alopecia
- Any autoimmune condition.

with type 1 diabetes mellitus or 5% of cases of autoimmune polyglandular syndrome with or without Addison disease. Children with Down, Turner, Noonan and Klinefelter syndromes, juvenile idiopathic arthritis, and systemic lupus erythematosus tend to have a predisposition to develop CLT.

The other causes of childhood hypothyroidism **(Box 1)** are congenital in origin but presenting later in childhood, noted especially with rapid growth during puberty, as in thyroid dyshormonogenesis with a goiter, or ectopic thyroid. Iodine deficiency during pregnancy can lead to simultaneous maternal and fetal hypothyroidism, resulting in irreversible mental retardation (so called endemic cretinism). This was a major public health problem in India, but with mandatory iodization of salt, is fortunately less often encountered now.

Pathogenesis

In CLT, diffuse lymphocytic infiltration occurs with fibrosis, parenchymal atrophy, and eosinophilic changes in acinar cells. Iodine storage becomes defective and synthesis of thyroxine is poor. Two forms of CLT are recognized, viz. goitrous and atrophic. Goitrous form is more common with diffusely enlarged thyroid caused by elevated serum TSH or autoimmune invasion by lymphocytes. In atrophic form, the resulting small gland causes severe hypothyroidism clinically.

Clinical Features

The clinical features of acquired hypothyroidism are listed in **Box 3**. Lethargy, fatigue, decreased activity, poor growth velocity and increased weight for height are frequent. The other common symptoms are dry skin and hair, constipation and cold intolerance. Unlike children with hyperthyroidism seen with poor concentration and lowered school performance, those with hypothyroidism have good academic scores (but may temporarily

BOX 3 Clinical features of hypothyroidism in children

Symptoms
- Lethargy; somnolence
- Low level of physical activity
- Normal or poor school performance
- Poor appetite but increased weight gain
- Dry skin
- Cold intolerance
- Constipation
- Delayed puberty
- Precocious puberty (rare)
- Family history of thyroid or autoimmune disorders

Signs
- Pallor
- Poor height velocity; short stature
- Increased weight for height
- Myxedema of face
- Goiter
- Absent or atrophic thyroid
- Bradycardia
- Cold extremities
- Decreased pulse rate
- Proximal myopathy
- Delayed relaxation phase of ankle jerk
- Delayed dentition
- Delayed puberty
- Delayed bone age.

deteriorate with initiation of thyroxine replacement). In many cases, symptoms and signs may have been present for months or years without being recognized.

Differential Diagnosis

Clinical diagnosis of hypothyroidism must be entertained in all of the following conditions: prolonged constipation, mood disorder (depression), short stature, malabsorption and malnutrition. Hypothyroidism will need also to be ruled out prior to making a diagnosis of constitutional growth delay or growth hormone deficiency.

Laboratory Tests

It is important to interpret thyroid function tests in children based on the normal range of hormone values for different ages **(Table 3)**. Low serum T4 (or free T4) and elevated serum TSH concentrations indicate primary hypothyroidism. T3 estimation is not useful as it may often be normal in hypothyroidism. If serum T4 or free T4 levels are low with normal or low serum TSH value, secondary or tertiary hypothyroidism should be suspected, but TBG deficiency should be ruled out. TRH stimulation test will help distinction between secondary and tertiary hypothyroidism. In secondary hypothyroidism, TRH will not elicit TSH response but in tertiary hypothyroidism, increased TSH response will be seen.

In CLT, anti-TG and anti-TPO antibody titers are increased and are useful markers for diagnosis. Ultrasonography, thyroid nuclear scan and fine needle aspiration cytology are indicated in the presence of a thyroid nodule. Children with predisposing factors such as type 1 diabetes mellitus, Down syndrome and conditions mentioned in **Box 2** should be monitored annually with thyroid function tests.

Histology of CLT demonstrates lymphocytic infiltration, formation of lymphoid follicles and follicular cell hyperplasia.

Management

Thyroxine replacement therapy using levothyroxine is the mainstay of treatment in hypothyroidism and with regular and continuous therapy; the symptoms disappear with remarkable overall improvement. The dose of levothyroxine for different age groups is given in **Table 4**.

Alternatively, a dose of 100 µg/m^2/day may also be used. The goal is to keep serum free T4 in the mid normal range and TSH in the normal range. Nearly 20% of children with CLT recover, become euthyroid and do not require lifelong thyroxine replacement. After attaining puberty, a 6-month trial of stopping thyroxine may be considered with serial measurements of free T4 and TSH every 3 months. In children with coexisting hypopituitarism or adrenal insufficiency or in those with chronic untreated hypothyroidism, glucocorticoid therapy should always precede thyroxine replacement to reduce the risk of adrenal crisis which may arise from enhanced metabolic needs induced rapidly by thyroxine replacement.

Prognosis

Prognosis is good if the diagnosis is made early without any delay and treatment begun. It also depends on the age at diagnosis and

Table 4 The dose of levothyroxine for different age groups

Age	Dose of thyroxine (µg/kg/day)
6–12 months	5–8
1–3 years	4–6
3–10 years	3–5
10–18 years	2–4

the duration of hypothyroidism. If symptoms were longstanding prior to therapy, recovery of physical stature is not always possible. Permanent intellectual or neurological deficits are less likely if age at diagnosis is beyond 3 years. Children with acquired hypothyroidism who receive adequate treatment at least 5 years before the onset of puberty may attain their genetic potential for final adult height.

SUBCLINICAL HYPOTHYROIDISM

Subclinical hypothyroidism (SCH) is defined as a normal serum total or free T4 level and a mildly elevated TSH (typically 5–10 mU/L). While this is common in children, treatment is controversial since there are currently no specific guidelines on management. Several recent pediatric studies indicate that progression of SCH to overt hypothyroidism is uncommon and that over a period of several years, elevated TSH usually either normalizes or persists without rising and without the clinical picture of hypothyroidism emerging. The etiology appears to be multifactorial, with some cases representing minor developmental abnormalities, some related to obesity, some to mild autoimmune thyroiditis, and some associated with mutations in the gene for the TSH receptor. There are no conclusive pediatric studies showing clinical benefit of treating these children with thyroid hormone, but additional studies in this area are needed. Since few cases of pediatric SCH progress to overt hypothyroidism, treatment may be deferred and periodic follow-up testing undertaken. Elevated thyroid antibodies or presence of a goiter are being considered risk factors for development of eventual overt hypothyroidism. If over a period of 2 years, the thyroid profile remains stable without increase in serum TSH, further periodic monitoring is not required.

SICK EUTHYROID SYNDROME

In nonthyroidal conditions such as acute or chronic severe illness, surgery, trauma, fasting, malnutrition and use of certain drugs, the classic findings of low T4 and free T4, low T3 with a low or normal TSH are not uncommon. The finding of elevated reverse T3 will confirm this disorder. Thyroid hormone replacement is not needed because the disorder resolves with amelioration of the underlying disease.

The mechanism is as follows: T4 5'-deiodinase enzyme converts T4 in peripheral tissues to the active hormone T3 and also helps in clearing reverse T3, which is a byproduct of T4 metabolism. With several nonthyroidal disorders listed above, 5'-deiodinase activity is inhibited resulting in low T3 production and elevated reverse T3 level.

THYROIDITIS

Thyroiditis includes: (1) acute suppurative thyroiditis due to bacterial infection, (2) subacute thyroiditis following a viral infection and (3) chronic thyroiditis, usually autoimmune in nature and the most common of the three types mentioned here. Autoimmune thyroiditis has been discussed in detail under acquired hypothyroidism.

Acute suppurative thyroiditis mostly involves the left lobe of the thyroid and is caused by *Staphylococcus aureus, Streptococcus haemolyticus* and pneumococci but also occasionally by aerobic and anaerobic bacteria. It is rare in children. Painful thyroid suggests suppuration. It may progress to abscess formation, and hence if diagnosed promptly and with appropriate antibiotics, this can be avoided.

Acute thyroiditis presents with fever, malaise, swollen tender thyroid. Neck pain is often unilateral and radiates to the mandible, ears or occiput. Sore throat, hoarseness of voice and dysphagia are common. Leukocytosis with a shift to the left is common; ESR is elevated and thyroid function tests will demonstrate elevated serum T4 and T3 levels, released by the inflammation into the circulation. Unlike in Graves' disease, radioiodine tracer uptake is low. Ultrasonography will be useful to identify thyroid abscess. Treatment is by appropriate antibiotic cover and liberal use of anti-inflammatory drugs.

In *subacute thyroiditis*, initial symptoms occasionally may suggest hyperthyroidism. Low grade fever, weakness and signs of systemic illness may be present. It is usually self-limiting and only supportive measures such as anti-inflammatory drugs are used to reduce discomfort and provide relief. Propranolol can be used to reduce signs and symptoms of hyperthyroidism.

> ## IN A NUTSHELL
> 1. Normal values of thyroid function tests are age-specific and hence interpretation of results needs to be based on age range.
> 2. The aim of treatment is to preserve or achieve normal growth and cognitive outcome and hence prompt recognition and initiation of treatment with good compliance will be essential.

Chapter 44.7
Newborn Screening for Congenital Hypothyroidism
Anna Simon

Newborn screening (NBS) is performed for diseases which are not evident clinically at birth, have serious irreversible consequences if treated late, have an excellent outcome if treated early, have a reliable diagnostic test, and available therapy. They should be common enough to justify economic costs. Screening for congenital hypothyroidism (CH) satisfies the prerequisites for a screening program. Unidentified CH has a significant negative impact on neurodevelopmental outcome, accurate biochemical assessments to confirm diagnosis are available and improved outcomes are definite with early intervention. It also is cost effective and acceptable to families. The high sensitivity and specificity of newer TSH assays make it a very useful screening test.

Neonatal thyroid screening is part of the national screening program in most developed countries. The incidence of CH is 1:3,000 to 1:4,000 as reported from countries where screening programs are ongoing over the last few decades. A higher prevalence has been reported from the Middle East and Asian countries and is likely in regions with severe iodine deficiency. Reports from India suggest that the incidence of CH in India is much higher than that reported in Western literature, approximately 1 in 1,100–1,200 newborns.

If the NBS program tests for other metabolic diseases, some of which require a specific metabolite to accumulate in the blood after feeding begins, then the most convenient specimen is blood from a heel-prick collected on special filter paper cards. This specimen is ideally collected between 2 days and 5 days of age (or at discharge from the hospital, if this occurs earlier). Cord blood TSH has also been used successfully for CH screening, especially when other diseases are not included in the NBS program. In this case, venous blood from an umbilical vein of the placenta can be collected in a vial (if serum TSH will be performed in the same hospital) or on filter paper (for transport to a central lab).

PRIMARY TSH SCREENING

Primary TSH screening is the most popular CH screening strategy nowadays because of the high sensitivity and specificity of TSH assays. Primary CH screening has been proved to be effective by using cord blood or blood collected after 36 hours of age (The physiological neonatal TSH surge precludes accurate interpretation of samples taken before 36–48 hours). Blood is spotted onto filter paper, allowed to dry and eluted into buffer for the analysis of TSH. A primary TSH test strategy will detect infants with mild or *subclinical* hypothyroidism but will not detect infants with secondary or central hypothyroidism and premature infants with *delayed TSH rise*.

PRIMARY T4 SCREENING

Many screening programs in USA undertake an initial primary T4 test, with a follow-up TSH. This primary T4 with follow-up TSH test strategy has the advantage of detecting some infants with secondary or central hypothyroidism and infants with *delayed TSH rise*.

COMBINED TSH AND T4 SCREENING

Combined TSH and T4 screening will have the advantage of detecting most cases of primary hypothyroidism, central hypothyroidism and babies with delayed TSH rise, but will be less cost effective.

CONFIRMATION OF SCREENING RESULTS

Once an infant has been detected with abnormal thyroid screening tests, they should be recalled immediately for examination, and a venous blood sample is obtained for confirmatory serum testing. Serum TSH and either free T4 or total T4 are estimated to confirm the diagnosis. It is important to compare the serum results with age normal reference ranges. The TSH can be as high as 39 mU/L in the first 72 hours due to the physiological TSH surge that occurs shortly after birth. Thereafter, the TSH values decline to an upper limit of 10 mU/L at 1–2 weeks of life. Nuclear imaging and ultrasound of the thyroid gland are useful to confirm the etiology and plan management. Estimation of thyroglobulin, TBG and maternal thyroid antibodies will help to further categorize the thyroid disorder. Several advanced laboratories also offer genetic mutational analysis to confirm both primary and secondary CH.

Confirmation of hypothyroid state before replacement is important to prevent the side-effects of unnecessary treatment with *l*-thyroxine. Treatment should begin latest by 2 weeks of age.

SCREENING IN SPECIAL CATEGORIES

Modified strategies and specific biochemical criteria should be used for screening of preterms, low birthweight babies and multiple births. This group of babies are at risk for transient and permanent CH. NBS programs should adapt cut-off values according to birthweight, gestational age, and age at sampling. As the hypothalamic-pituitary-thyroid axis is immature in preterm babies resulting in a delayed TSH rise, repeat and multiple sampling strategies should be instituted at regular intervals to screen for CH. The interpretation of screening results should take into account the results of all the specimens assayed in a multiple sampling.

IN A NUTSHELL

1. The high sensitivity and specificity of newer TSH assays make it a very useful screening test for CH.
2. The specimen is ideally collected between 2 days and 5 days of age on a filter paper.
3. Confirmation of hypothyroid state before replacement is important to prevent the side-effects of unnecessary treatment with *l*-thyroxine.
4. Treatment should begin latest by 2 weeks of age.
5. Modified strategies and specific biochemical criteria should be used for screening of preterms, low birthweight babies and multiple births.

Chapter 44.8
Hyperthyroidism
Sobha Kumar

Hyperthyroidism is a rare form of thyroid disorder in children, in contrast to hypothyroidism. Patients present with over-activity of basal metabolism due to overproduction of thyroid hormone.

EPIDEMIOLOGY

In an epidemiological study from Cochin (Kochi), subclinical and overt hyperthyroidism were present in 1.6% and 1.3% of subjects participating in a community survey. In a hospital-based study of women from Puducherry, subclinical and overt hyperthyroidism were present in 0.6% and 1.2% of subjects. More than a third of community-detected hyperthyroid cases had positive antithyroid peroxidase (TPO) antibodies, and about 39% of these subjects had a goiter. Graves' disease (GD) is the most common etiology (seen in 90% of cases), other causes being rare **(Box 1)**.

GRAVES' DISEASE

Graves' disease is an autoimmune condition, occurring due to the production of thyroid-stimulating immunoglobulins, which stimulate the thyroid-stimulating hormone (TSH) receptor. GD occurs in genetically predisposed individuals. Predisposition to GD is associated with the major histocompatibility complex, the high-risk alleles being HLA B8, HLA DR-3 and less commonly HLA DQA1. There is a female preponderance, the female-to-male prevalence ratio being 6:1. It is more common in adolescence, but the disease is more severe in prepubertal children.

Other autoimmune diseases that can be associated with GD are type 1 diabetes mellitus, Addison disease, systemic lupus erythematosus, and myasthenia gravis. Syndromes associated with GD include Down syndrome and rarely DiGeorge syndrome.

Pathogenesis

The TSH receptor antibody mimics the action of TSH on its receptor and causes stimulation of adenyl cyclase which in turn causes thyroid hormonogenesis and growth. Hyperthyroidism and thyromegaly of GD are mediated through immunoglobulin G (IgG1) that binds to the extracellular domain of the TSH receptor and stimulates follicular cell growth and function. The major source of TSH receptor antibody production appears to be intrathyroidal lymphocytes, lymphocytes in spleen, lymph nodes, bone marrow and peripheral blood.

The proposed mechanism and control of stimulating TSH receptor antibody production include deficiency of specific suppressor T-cell function, breakdown of idiotype and anti-idiotype network of β-lymphocytes immune regulation, and increased frequency of antibodies to certain serotypes of *Yersinia enterocolitica*.

BOX 1 Causes of thyrotoxicosis in children

- Graves' disease and Hashimoto hyperthyroidism
- Toxic adenoma (autonomously functioning thyroid nodule)
- Toxic multinodular goiter including functional nonimmune hyperthyroidism and McCune-Albright syndrome
- Acute and subacute thyroiditis
- Neonatal thyrotoxicosis
- Thyrotoxicosis factitia (thyroid-hormone overdose)
- Central hyperthyroidism (TSH-producing adenoma)
- Thyroid-hormone resistance

Clinical Features

The symptoms include increased appetite, weight loss despite increased food intake, tremors, irritability, inability to sleep, proximal muscle weakness, headache and palpitations. Shortened attention span and emotional lability may lead to severe behavioral and school difficulties. Other symptoms include polyuria and nocturia, increase in linear growth and secondary amenorrhea.

The thyroid is diffusely enlarged, and the gland is soft, fleshy and smooth with a bruit. The hair texture is fine. Excess activity manifests as fidgetiness. There is a fine tremor of the tongue and fingers. Tachycardia and a wide pulse pressure are typical. Young children can manifest with diarrhea, transitory language delay, or craniosynostosis.

Eye abnormalities include signs of sympathetic hyperactivity (lid lag, lid retraction and globe lag) and those of infiltrative ophthalmopathy characterized by exophthalmos **(Fig. 1)**, conjunctival chemosis or edema, lid edema, and conjunctival redness; and in severe cases ophthalmoplegia, periorbital ecchymosis, diplopia, uveitis, and corneal ulceration. Accumulation of glycosaminoglycans in connective tissue components of orbital fat and muscles, extraocular muscle dysfunction, edema, inflammation, and fibrosis of endomysial connective tissues contribute to symptoms. Orbital antigens share unique structural characteristic with antigens of thyroid gland. Eye findings are less severe in children as compared to adults with thyrotoxicosis and improve in association with control of hyperthyroidism. Severe cases are treated with oral corticosteroids, orbital irradiation and surgical decompression.

Other features which point to an autoimmune origin are associations with vitiligo, systemic vasculitis, Addison disease, type 1 diabetes mellitus, myasthenia gravis, and pernicious anemia.

Laboratory Investigations

Thyroid-stimulating hormone (second- or third-generation assay) is suppressed and T4 or free T4 is elevated. Serum T3 is useful at the time of diagnosis, as some patients may have only elevated T3 and not T4. TSH receptor antibody test if available will be found to be positive. Baseline complete and differential WBC and serum alanine aminotransferase (ALT or SGPT) may be relevant as these are often abnormal due to GD itself, and if shown to be so before start of therapy, will not be taken as indicative of adverse effects of antithyroid medication. Thyroglobulin and TPO antibodies are present in thyrotoxicosis due to Hashimoto thyroiditis and subacute thyroiditis.

Treatment
